

# The Geography of Job Tasks

Enghin Atalay Sebastian Sotelo Daniel Tannenbaum\*

August 21, 2022

## Abstract

We introduce new measurement tools to understand the sources of earnings differences across space. Based on the natural language employers use in job vacancy text, we develop granular measures of job tasks and of worker specialization. We find that jobs in larger commuting zones involve greater interpersonal interactions and have higher computer software requirements. Between 10 and 50 percent of task and technology variation between large and small commuting zones exists within occupations. Further, workers in larger markets are more specialized within occupations. Tasks, technologies, and worker specialization account for a substantial portion of the market size premium even within occupations.

Tannenbaum: Department of Economics, University of Nebraska-Lincoln. We thank Reid Gahan, Billy Huang, and Ryan Kobler for outstanding research assistance and Barbara Nordin for excellent editorial assistance. We thank seminar participants at the 2019 Society of Labor Economists conference, the 2019 Urban Economics Association conference, the UNL labor reading group, the Federal Reserve Bank of Philadelphia, the 2022 ASSA annual meetings, the Bureau of Labor Statistics, and Adrien Bilal, Jeffrey Lin, and Gregor Schubert for valuable feedback. We thank the Washington Center for Equitable Growth and the Russell Sage Foundation (grant #92-18-05) for financial support. Sotelo thanks the IES at Princeton for its hospitality during part of this research. The views expressed in this paper are solely those of the authors and do not necessarily reflect the views of the Federal Reserve Bank of Philadelphia or the Federal Reserve System.

# 1 Introduction

Geographic inequality is a pervasive feature of the U.S. labor market. Average wages, the college wage premium, and the wage gap between white-collar and blue-collar occupations all increase with the size of the labor market. Furthermore, different labor markets foster distinct types of work. For example, managerial, financial, and computer occupations are overrepresented in large labor markets, while maintenance, production, and material moving occupations employ a greater share of workers in small labor markets.

While economists have studied how jobs vary with market size, prior research has been limited in its ability to characterize spatial differences in the nature of work. Analyses of job content, applying national datasets such as O\*NET, cannot directly measure the extent to which occupations vary across markets. This approach might be apt for some occupations—for example, food preparation workers may perform similar activities in Ann Arbor, Michigan as in Dallas, Texas. But for other occupations, job tasks and technologies likely vary with the size of the labor market. For example, financial analysts in Hastings, Nebraska may perform fundamentally different tasks compared to those in New York City. Existing datasets are silent on these differences.

In this paper, we study the geography of job tasks and technology requirements in the United States. We do so using a novel approach to measurement applied to an increasingly utilized data source: the text of online job ads. We provide new evidence for three mechanisms behind the commuting zone (CZ) size-wage premium: interpersonal interactions and coordination, the adoption of new technologies, and worker specialization.

We leverage the job description text and tools from natural language processing to extract detailed information about job tasks and technologies. Our measures are not fixed at the occupation level, and capture differences in task content within and across regions. As we show in this paper, work is different across CZs, even within occupations, and this heterogeneity is important for understanding both the CZ size-wage premium and the increased skill premium in larger CZs.

We take two approaches to task measurement. The first approach, following our prior work on newspaper job postings ([Atalay et al., 2018, 2020](#)), maps words in job descriptions into routine and non-routine task categories. Our second approach uses tools from natural language processing to define tasks as verb-noun pairs that appear in job descriptions. This second approach is new to this paper and departs from prior research on tasks, in which it is common to select a subset of survey questions from data sources such as O\*NET and then classify these items into economically meaningful task categories ([Spitz-Oener, 2006; Autor, 2013](#)). There are two key advantages to our more granular approach to task measurement.

First, it reduces the amount of researcher discretion in classifying tasks, and second, because of its high resolution, it allows us to measure how specialized jobs are—i.e., how far apart workers are in task space, within firms or occupations.

Our main empirical analysis introduces several facts regarding the geography of work in the United States. We first show that analytic and interactive tasks have a steep positive gradient in market size: Relative to jobs in the bottom population decile, jobs in the top population decile have 0.30 standard deviations (s.d.) higher intensity of non-routine analytic tasks and 0.24 s.d. higher intensity of interactive tasks. In addition, these jobs have 0.18 s.d. lower intensity of routine manual tasks. A large part of these gradients is due to occupational composition, but even after conditioning on narrowly defined occupation categories (six-digit SOC) about 16 percent of the gradient between largest and smallest CZs for non-routine analytic tasks, 27 percent of the gradient for non-routine interactive tasks, and 53 percent of the gradient for routine manual tasks remains. We further decompose interactive tasks into those that capture interactions outside the firm and those that capture interactions within the firm. The CZ size gradient is positive for both external and internal interactive tasks, and these relationships are more pronounced for jobs requiring a college degree.<sup>1</sup> Our subsequent analysis using the granular task measures echoes these findings at a much higher resolution. The verb-noun pairs with the steepest gradients with CZ size demonstrate the importance of problem-solving (“managing projects,” “developing strategies,” “problem-solving skills”) and communication and worker interactions (“written communication,” “maintaining relationships”) in large CZs.

We next consider whether technological requirements—specifically the use of computer software—are more likely to be mentioned in job descriptions in larger markets, and how this gradient differs for college- and non-college-requiring jobs. Measuring technology requirements as the appearance of O\*NET’s Hot Technologies in the job descriptions, we find that technology requirements increase steeply with market size, with approximately one-and-a-half times as many technology mentions in the largest CZs as in the smallest. About 11 percent of the gradient remains after conditioning on six-digit occupational categories. Moreover, the technology gradient is present only for jobs requiring a college degree, and vanishes for jobs requiring only high school. We also measure the specific types of technologies demanded by education level, and we find that technologies with the steepest gradient for college degree holders involve computer programming (e.g., Python, JavaScript, and Linux), while for high school diploma holders, they involve data entry and word processing (e.g.,

---

<sup>1</sup>We also show that jobs that are jointly intensive in interactive and analytic tasks are overrepresented in large markets. Thus, the increasing aggregate importance of social and analytic tasks since the 1980s ([Deming, 2017](#)) is mirrored by the differential task content between small and large labor markets.

Microsoft Excel, Microsoft Outlook, Microsoft Word).<sup>2</sup>

Our paper also introduces a novel approach for measuring the degree of worker specialization using the content of job descriptions. We measure the degree of specialization between two jobs as the cosine dissimilarity between vectors representing their task contents. The motivation behind this measure is that jobs with less overlap in tasks are more dissimilar and therefore more specialized relative to one another. For this exercise, we represent a job's task content as a vector of verb-noun pairs from the job description text. We show that task specialization is increasing in market size, and this relationship holds along a number of dimensions—within occupations, within firms, and between firms. These relationships are stronger for firms in the nontradable sector.

Workers in top population decile CZs earn 33.5 log points more than those residing in bottom population CZs. Even within occupations, this premium is 30.1 log points. In a final step of our analysis, we show that our new technology and specialization measures are associated with large differences in wages and skill premia between smaller and larger labor markets. Within-occupation heterogeneity in interactive tasks, technology usage, and specialization account for 21 percent (6.2 log points out of a total of 30.1) of the difference in wages between workers in top and bottom population decile commuting zones, and 23 percent (9.3 log points out of a total of 40.8) when we subset to white-collar occupations. We interpret these regressions descriptively, since the premia on tasks and technologies may in part reflect worker sorting on unobservables correlated with job characteristics. Nevertheless, they show that jobs differ between large and small labor markets—even within occupations—in ways that have been previously unmeasured and are reflected in wages. In addition, our evidence suggests that worker sorting is driven in part by the particular job tasks and technologies that employers demand.

Our paper contributes to research on geographic inequality (Glaeser and Maré, 2001; Moretti, 2013a; Diamond, 2016; Frank et al., 2018) by using job postings data to study the geography of tasks and technologies.<sup>3</sup> Worker interactions have long been pointed to as a source of productivity gains in cities (Marshall, 1890; Jacobs, 1969), and recent research studies worker interactions as a source of agglomeration, both theoretically (Davis and Dingel, 2019) and empirically (Bacolod et al., 2009b; Michaels et al., 2018; Rossi-Hansberg et al.,

---

<sup>2</sup>These results complement an expanding literature on the spatial distribution of technology adoption. Eckert et al. (2020) emphasize the impact of cheaper ICTs on services that agglomerate in large cities and that focus on the creation and communication of information. Bloom et al. (2020) examine where new technologies develop and how they diffuse. Eeckhout et al. (2021) find that IT investments have impacted job and wage polarization since the 1980s.

<sup>3</sup>Previous research exploits job vacancy postings across different labor markets, without seeking to explain the CZ size premium (Hershbein and Kahn, 2018; Deming and Kahn, 2018; Hemelt et al., 2020).

2019; Moretti, 2021). Prior research also shows that new patents and occupational titles are more likely to appear in cities (Carlino et al., 2007; Lin, 2011), suggesting that innovation and technology adoption is concentrated in larger CZs. Using the text of job vacancies, we allow for within-occupation heterogeneity in job tasks and technologies, and introduce a new approach to task measurement, which uses natural language processing and requires fewer ex ante restrictions relative to widely used O\*NET scales and categories. We show that worker interactions and the adoption of new technologies increase in CZ size, and the gradients are particularly strong for college-educated workers. We find substantial within-occupation heterogeneity that is important for explaining CZ size-wage premia and the differential returns to work faced by white- and blue-collar workers. These findings suggest there are limits to worker mobility, even within the same occupation.

We also contribute to the literature that relates productivity and the division of labor to the extent of the market (Young, 1928; Stigler, 1951; Kim, 1989; Becker and Murphy, 1992). Recent work finds greater occupational diversity in cities (Duranton and Jayet, 2011; Tian, 2019). Moretti (2013b) and Dauth et al. (2022) provide evidence for more efficient matching of workers and firms in cities. Our contribution is to measure the degree of specialization directly, by first extracting a high-dimensional vector of work content from job ads, and then measuring the distance between jobs in task space. We show that worker specialization increases in CZ size and that this increased specialization accounts for a substantial portion of the CZ size-wage premium.

## 2 Data and Measurement

Our data source is a comprehensive database of online job ads, posted between January 2012 and March 2017, which we purchased from Economic Modeling Specialists International (EMSI, 2017). This dataset is similar to Burning Glass Technologies (Burning Glass), which has been used in recent work to study the labor market (Hershbein and Kahn, 2018; Deming and Kahn, 2018; Modestino et al., 2020). Like Burning Glass, EMSI data are proprietary and assembled using web crawlers that extract job vacancy postings from all major online job boards; EMSI also removes duplicate postings that appear across boards. An advantage of the EMSI data for our purposes is that it contains all of the original job ad text. To reduce computational time, we use a 5 percent random sample of the data (7.2 million ads).<sup>4</sup>

---

<sup>4</sup>EMSI is the preferred data source for our purposes because it contains each ad's complete job description text, which is ideal for extracting job tasks and measuring specialization. By contrast, the version of Burning Glass to which we also have access provides a combination of tasks, skills, and technologies. As a robustness check, we reproduce our main results using Burning Glass data and report them in Appendix C.4. Our results are similar with this alternate data source.

In addition to the full text content of each ad, EMSI provides fields for the educational requirement of the job, the firm name (which we use to create firm identifiers), the firm’s industry (six-digit NAICS), the occupation code (six-digit SOC), and the job location (county FIPS code). We map FIPS codes to commuting zones (CZs) following [Autor et al. \(2019\)](#). We adopt the CZ as our geographic unit of analysis and refer to CZs throughout as local labor markets. Appendix A.1 provides descriptive statistics for the CZs in the sample, including population and number of ads by CZ decile. We exclude ads with fewer than the 1st and more than the 95th percentile word count.<sup>5</sup> We make a few additional minor restrictions, which are detailed in Appendix A.2, and which leave us with a sample of 6.3 million ads for the occupational analysis and 5.6 million ads for the firm-level analysis.

For the several exercises that require wages at the occupation level and for the construction of employment weights, we use the 2010-2017 American Community Survey (ACS) ([Ruggles et al., 2020](#)), and restrict the sample to full-time, full-year workers, defined as working at least 40 weeks in the past year and 35 or more hours per week. Our measure of wages is total annual pre-tax wage and salary income (“wages” throughout the paper), which we adjust by CPI-U to constant 2012 dollars before averaging to the four-digit SOC-by-CZ cell. We link job ads data to the ACS by four-digit SOC and CZ, and therefore when wage regressions include occupation fixed effects, these are defined at the four-digit level. We use four-digit SOCs for this analysis because of the larger available sample sizes in the ACS SOC×CZ cells.<sup>6</sup> In a robustness analysis, we use Burning Glass data, which contains wages extracted from job ads (see Appendix C.5).

## 2.1 Measuring Tasks: Extraction and Classification

We extract job tasks from the job descriptions using two approaches. Our first approach follows our earlier work ([Atalay et al., 2018, 2020](#)) and maps keywords in the job descriptions to task categories. We map words into five task categories—non-routine interactive, non-routine analytic, non-routine manual, routine cognitive, and routine manual—following the categorization of [Spitz-Oener \(2006\)](#). We also map words into O\*NET work activities, to validate our text-based task measures and to study different types of interactive tasks. See

---

<sup>5</sup>Dropping extremely short ads removes those that are unlikely to have meaningful task information, while dropping exceedingly long ads helps reduce computation time.

<sup>6</sup>In principle, we could measure wages at a finer level of detail, using either wages from the individual job ads or from the Occupational Employment Statistics Survey (OES). While the OES measures wages at the six-digit occupation level within certain metro areas, these data have their own disadvantages: (i) they do not cover non-metro areas; (ii) the level of detail varies according to the metro area size (i.e., for smaller metro areas they do not have wage information at the six-digit level, or even at the four-digit level for very small metro areas); and (iii) there is no information on wages by worker education, which we control for in some of our specifications.

Appendix A.5 for more details on the word mappings. For job ad  $j$  and task category  $k$ , our measure of task intensity is the number of distinct task-specific word mentions per 1,000 ad words.<sup>7</sup> We standardize each task to have mean zero and standard deviation one across all ads.<sup>8</sup>

Our second approach is new to this paper and uses verb-noun pairs in the job descriptions to define the set of job tasks. The motivation behind this approach is that job tasks are the activities required of workers in the position. By pairing verbs with nouns we more narrowly define the action and are able to distinguish between different types of activities. For example, “develop relationships” is distinct from “develop strategies,” and “lead team” is distinct from “lead customers.” This approach is less reliant on researcher discretion, permits task measurement at a granular level, and thus allows us to measure specialization among jobs within the same occupation, industry, or firm.

There are two steps to the task extraction process: first, to define the set of tasks, and second, to vectorize ads according to the set of tasks defined in the first step. To proceed with the first step, we define a task as a (verb stem, noun stem) pair that occurs within the same sentence.

To ensure the verb-noun pairs that we extract are actually tasks and not firm or worker characteristics, we first isolate the section of the text that pertains to job tasks. We search for keywords in the text that suggest a list of tasks will follow. The keywords we use are “duties,” “summary,” “description,” and “tasks.” We isolate the section of text that begins at one of these keywords through the end of the ad.<sup>9</sup> Then, using Python’s NLTK library, which features a sentence tokenizer and parts-of-speech tagger, we extract each verb and the next noun in each sentence, ignoring other parts of speech that may appear in between. Hence, whether the job ad says “perform commercial, residential, and industrial electrical maintenance,” as it does in the sample ad of Table B.1, or simply “perform maintenance,” our algorithm will record “perform maintenance” as the task. If multiple verbs correspond to the same noun (for instance, “serve and assist customers”), our algorithm extracts two

<sup>7</sup>We count repeated use of the same word only once. Hence, the repetitiveness of the job description does not inflate the task intensity of the ad. The use of different task keywords, such as “analyze” and “evaluate,” will each be counted and will increase the task intensity measure.

<sup>8</sup>In Atalay et al. (2020), we show robustness to the choice of word mappings—e.g., by including and excluding synonyms of words in the mapping to tasks—and to alternative task units.

<sup>9</sup>This step significantly improves the precision of the task extraction. Note that not all ads will have these keywords, and hence an important check is whether the presence of these words varies systematically with CZ size. Figure A.11 investigates this relationship and finds little evidence for a systematic pattern. In step 2, when we vectorize all job ads based on the task vocabulary created in this step, we do not restrict the data to jobs that include these keywords. Also, in step 2, we perform the vectorization on all ad text, not just the portion of text that follows a keyword.

distinct tasks: “serve customers” and “assist customers.”<sup>10</sup> Verbs and nouns are stemmed so that variation in verb and noun forms do not affect the analysis (e.g., “assist customers” and “assisting customers” are treated as the same task).

We choose 500 tasks to balance the advantage of comprehensively characterizing jobs’ tasks against the costs of computational time. We reproduce the key results using the 2,000 most common tasks (a higher resolution) and using the 300 most common tasks (a lower resolution) in Appendices C.1 and C.3 and obtain nearly identical results. We also show that when we use a natural language processing approach to aggregate granular tasks that are similar in meaning (e.g., “identifies problems” and “resolve issue”) we get nearly identical results (see Appendix C.2).

In the second step, we search through the full text of each ad for the appearance of each of these 500 verb-noun pairs and vectorize each job ad.<sup>11</sup> Verb-noun pairs that appear multiple times in an ad are counted only once, and hence each element of the vector is a zero or one. Table B.1 provides two example job ads with their full text, along with the verb-noun pairs extracted by the algorithm.

In our main analysis with 500 tasks, we exclude 101 verb-noun pairs that in our judgment do not correspond to job tasks, such as “send resume” and “is position,” and hence the number of tasks used in the analysis is 399. Appendix B.1 lists these 399 verb-noun pairs and the 101 excluded pairs.<sup>12</sup>

The 10 most common tasks, from most to least frequent, are: “written communication,” “working team,” “provide customer-service,” “provide service,” “lifting pounds,” “providing support,” “build relationships,” “ensure compliance,” “assisting customers,” and “provide customer.” While the task extraction process is not perfect, a key strength of our approach is that it allows the text used by employers, describing the jobs they intend to fill, to define the set of tasks.

To illustrate the value of natural language processing for extracting job tasks, Table 1 lists the most common tasks for each of four occupations: Electricians, Supervisors of Retail Sales, Registered Nurses, and Lawyers. The tasks are broadly aligned with our prior intuition for what workers in these different occupations do. For instance, Electricians need to “use

---

<sup>10</sup>We do not perform the analogous procedure when a verb is followed by a list of nouns (for instance, “assist customers and staff”); in this situation, our algorithm extracts one task—the verb and the first noun (“assist customers”).

<sup>11</sup>We use the entire job ad text when vectorizing, rather than a subset of the text. The reason is that not all ads have a section of text with keywords that indicate job tasks will follow. As a result, there is a tradeoff between being able to vectorize all ads and reducing bias from potentially counting instances of verb-nouns that do not refer to job tasks.

<sup>12</sup>In our robustness exercises with 2,000 tasks, we do not exclude any verb-noun pairs. Hence, our main analysis is not sensitive to the exclusion of selected verb-noun pairs.

hands,” “ensure compliance,” and “perform maintenance,” while Supervisors of Retail Sales must “provide customer-service,” “drive sales,” and “maintain inventory.” Registered Nurses “provide care,” “provide service,” and “make decisions,” while Lawyers must use “written communication,” “provide guidance,” “conduct research,” and “meet deadlines.” These descriptive results lend confidence to the approach of using these tasks to study the labor market.

## 2.2 Job Ads: Coverage, Representativeness, and Selection

Before using the content of online job ads to study the labor market, we must evaluate the coverage of job ads across space and whether online job ads are a reasonable representation of overall vacancies. In Appendices A.3 and A.4, we consider the coverage and representativeness of the online job ad data. We first document that our 5 percent sample of ads span four-digit SOC by CZ cells representing 98.3 percent of ACS employment. We then evaluate the representativeness of our data, comparing it to the Job Openings and Labor Turnover Survey (JOLTS) dataset. Consistent with a similar check in [Hershbein and Kahn \(2018\)](#), we find broad concurrence in the industry composition between the EMSI data and JOLTS. Finally, in Appendix A.4, we use the Current Population Survey (CPS) Computer and Internet Use Supplement to measure the propensity of workers to find employment through on-line job ads (as opposed to through other channels). The importance of online job ads is invariant to CZ size in the aggregate, within occupations, and separately for workers with and without a college degree.

## 2.3 Beyond O\*NET: The Usefulness of Job Ads for Studying the Labor Market

O\*NET is one of the most widely-used data sources for measuring job tasks, and it has been a valuable resource for research on topics ranging from the changing nature of work ([Deming, 2017](#)) to the labor market effects of technology ([Acemoglu and Autor, 2011](#)) and immigration ([Peri and Sparber, 2009](#)). Despite its popularity and usefulness, O\*NET faces a limitation of being based on surveys with small sample sizes—approximately 39 respondents per occupation and item ([Handel, 2016](#))—and offering measures at the occupation-level only.

Since O\*NET is the benchmark, we first examine how well job ads can approximate an O\*NET-based analysis of tasks and market size. Note that job ads represent vacancies—a flow—whereas O\*NET is a survey of employed workers—a stock. Therefore, we consider the extent to which vacancies capture information about employed workers. We construct O\*NET measures of job tasks following the selection of survey items and categorization of [Acemoglu and Autor \(2011\)](#), and construct occupation-level tasks using job ads following

the Spitz-Oener (2006) categorization described above. We then study the task gradient with market size using the two distinct occupation-level task measures (O\*NET v. job ads), where the variation in tasks across markets is due solely to variation in employment shares. We demonstrate in Appendix A.5 that the task gradients are strikingly similar across data sources.

Second, we extract occupation-level tasks from the text of job ads to mimic O\*NET work activities. For this exercise, we rely on words from O\*NET task descriptions and construct tasks in the job ads data based on these words. We show in Appendix A.5 that the occupation-level measures of O\*NET work activities that we construct from the text of online ads are highly correlated with those occupations' measures in the O\*NET database. Thus, the tasks extracted from the job ads reflect occupation-level content that is similar to the occupation-level content of O\*NET. Of course, job ad data have additional within-occupation variation in tasks that we are shutting down for these two validation exercises; in our main analysis, we leverage the additional within-occupation variation in tasks.<sup>13</sup>

Finally, to demonstrate the value of the within-occupation variation in tasks, we show that occupation-CZ task measures, constructed using job ads, account for variation in average wages at the occupation-CZ level, above and beyond what is captured by occupation fixed effects. These results are presented in Appendix B.6. The job ads data therefore capture occupational characteristics beyond what is available in O\*NET, and these characteristics are reflected in market wages.

### 3 The Geography of Tasks and Technologies

This section presents the main analysis of the geography of job tasks, technology requirements, and worker specialization.

#### 3.1 Job Tasks Across Space

We begin with our first approach to task measurement, and study how the five task categories (non-routine interactive, non-routine analytic, non-routine manual, routine cognitive, and routine manual) differ across labor markets of different sizes. For each task  $k$ , we regress task intensity  $t_{jn}^{(k)}$  of job ad  $j$  in market size decile  $n$  on indicators for market size decile. CZs are placed in market size deciles using employment weights so that each decile  $n$  has

---

<sup>13</sup>One survey that contains within-occupation variation in task measures—though with much smaller sample sizes and less granular geographic and task measurement—is the Princeton Data Improvement Initiative (PDII). In Appendix A.5, we study the within-occupation correlation of tasks measured in the PDII and tasks measured in job vacancies and find broad alignment between the two.

approximately the same number of employed workers. We estimate:

$$t_{jn}^{(k)} = \beta_0 + \sum_{n=2}^{10} D_{jn}\beta_n^{(k)} + \gamma' x_j + \epsilon_j, \quad (1)$$

where  $D_{jn}$  are indicators for market size decile  $n$ , with the 1st decile serving as the reference group, and  $x_j$  represents a control for ad length and, in some specifications, six-digit SOC fixed effects. The coefficients of interest,  $\beta_n^{(k)}$ , capture the task intensities relative to the 1st decile market size.<sup>14</sup> Standard errors are clustered at the commuting zone level.

Figure 1, panel I, plots the coefficients on market size decile,  $\beta_n^{(k)}$ , based on estimates of equation (1). The primary takeaway is that non-routine interactive and non-routine analytic tasks are increasing in market size, while routine manual tasks are decreasing in market size. According to panel I, jobs in population decile 10 have 0.24 s.d. greater intensity of non-routine interactive tasks and 0.30 s.d. greater intensity of non-routine analytic tasks, while having approximately 0.18 s.d. lower intensity of routine manual tasks. Panel II includes six-digit SOC fixed effects, and shows that the gradients diminish. This weaker gradient is unsurprising and indeed reassuring, since occupational categories are designed to group jobs by their work activities. Nevertheless, even within occupations, non-routine interactive and analytic tasks are mentioned more frequently (by 0.06 s.d. and 0.05 s.d., respectively), and routine manual tasks are mentioned less frequently (by 0.10 s.d.), in the top population decile CZs relative to the bottom decile. Hence, while much of the variation in job tasks across geography is captured by the composition of occupations, a strong gradient remains even within occupations, which is missed in standard data sources such as O\*NET. Taking the ratio of the point estimate for decile 10 in Panel II relative to the estimate for decile 10 in Panel I, about 16 percent of the gradient remains with six-digit SOC fixed effects for non-routine analytic tasks and 27 percent of the gradient remains for non-routine interactive tasks. For routine manual tasks, about 53 percent of the gradient remains.<sup>15</sup>

Our findings deepen our knowledge of how work differs across labor markets of different sizes, going beyond standard educational and occupational classifications. [Bacolod et al. \(2009a\)](#) document that the urban wage premium is partly a premium on cognitive and interactive skills and also that, in contrast, there is no urban premium on physical skills. In related work, [Bacolod et al. \(2009b\)](#) document that agglomeration increases the demand

---

<sup>14</sup>Section 3.4 presents the elasticities of tasks—as well as technologies and worker specialization—with respect to a continuous measure of log population, following a two-step procedure ([Combes and Gobillon, 2015](#)).

<sup>15</sup>In Appendix C.1, we perform a decomposition to further evaluate how much of the variation in tasks across geography is due to within- versus between-occupation variation in task content.

for interactive skills and the opportunities for specialization. These papers use a hedonic model, worker-level skill data, and occupation-level task data to study how the demand for tasks varies with geography. An advantage of our approach is that we are able to directly observe how jobs themselves vary across labor markets within occupations. This fine level of detail allows us to show that the extent to which occupations themselves vary across CZs accounts for a sizable share of these premia. We also show in Section 3.3 that workers and firms specialize more in larger markets in the space of tasks. Lastly, in Section 3.5 we show that these within-occupation differences have important implications for wage differentials.

We additionally explore whether the relationship between task contents and CZ size depends on a worker’s education level. Panels III through VI of Figure 1 present this analysis. Jobs requiring a college degree in large CZs are far more intensive in interactive and analytic tasks compared with those in smaller CZs, while this gradient is flat for jobs requiring only a high school diploma. Both within and between occupations, jobs in large CZs require different skills of workers with different education levels.

Finally, Figure C.1 shows that jobs that are *jointly* intensive in interactive and analytic tasks represent a greater share in large markets. Jobs that are intensive in both analytic and interactive tasks make up 12.3 percentage points more of jobs in the highest decile compared with the lowest decile. Jobs that are intensive in only analytic tasks but not interactive tasks make up only about 3.4 percentage points more of jobs in the highest decile. These qualitative findings also hold within occupations. In sum, the increasing importance over time of jobs that are jointly analytic and interactive (as documented by Deming, 2017) is mirrored in these jobs’ overrepresentation in large labor markets.

## Interactive Tasks Inside and Outside the Firm

Having demonstrated the importance of interactive tasks in large labor markets, we study the nature of interactive tasks and specifically assess the importance of interactions *inside* the firm relative to interactions *outside* the firm.

We use task measures that map to O\*NET task categories that separately measure external and internal interactive tasks.<sup>16</sup> We regress each task-intensity measure on commuting zone size deciles, with controls for ad length and, where indicated, six-digit SOC fixed effects. Figure 2 plots the coefficients on market size decile, with the 1st decile as the reference decile. This figure shows that both external-to-the-firm and internal-to-the-firm interactive

---

<sup>16</sup>We define *external interactive tasks* as O\*NET activities “Selling or Influencing Others” and “Communicating with Persons Outside Organization,” and we define *internal interactive tasks* as O\*NET work activities “Guiding, Directing, and Motivating Subordinates,” “Developing and Building Teams,” “Coaching and Developing Others,” “Coordinating the Work and Activities of Others,” and “Communicating with Supervisors, Peers, or Subordinates.” We list the word mappings in Appendix A.5.

tasks increase with market size. Compared with ads in the bottom population decile, ads in the top population decile mention internal interactive tasks (by 0.21 s.d.) and external interactive tasks (by 0.26 s.d.) more frequently. When we include six-digit SOC fixed effects, the gradients are 0.07 for both—about 30 percent as large.

Our results indicate that both types of interactive tasks—those related to interactions within and across firm boundaries—increase with market size. As far as we are aware, this is the first exercise to separately and jointly measure the CZ size gradient of external and internal interactions. Moreover, exploiting the richness of our data, in Figure C.2, we show that both of these gradients are largely driven by occupations requiring a college degree.

These results are important since they provide direct evidence about the micro mechanisms behind the structure of the firm and the spatial agglomeration of economic activity. Recent work, for example, has emphasized how productivity gains at the firm level are related to the ability to facilitate information flows within the firm (Garicano and Rossi-Hansberg, 2015), which we show happens more intensively in large labor markets. Other work, beginning with Marshall (1890), and more recently including Arzaghi and Henderson (2008) and Davis and Henderson (2008), argues that communication across firms—either among firms within the same industry or between customers and suppliers—is a key source behind agglomeration of economic activity. More broadly, we add to the evidence discussed in Davis and Dingel (2019) about cities as loci of interaction, showing that both internal and external interactions matter, and that skilled workers are key to these information flows. Underpinning all this work is the idea that large markets reduce the cost of face-to-face meetings, facilitating tacit knowledge flows among economic agents (Storper and Venables, 2004). Our empirical evidence demonstrates that both theories emphasizing information flows between and across firm boundaries are necessary to fully characterize labor markets, but with the proviso that the tacit knowledge flows shared in large CZs are primarily among college-educated workers.

## A Granular Approach to Measuring Tasks

Turning to our second approach to measuring tasks, we study the verb-noun pairs extracted from the text. We estimate equation (1) separately for each of the tasks, and collect the coefficients  $\hat{\beta}_{10}^{(k)}$ , which capture the relative difference in task  $k$  intensity between 10th decile market size and 1st decile market size. The coefficients are normalized by dividing by the standard deviation of the task and then sorted by magnitude. Table 2 presents the largest positive and largest negative estimates across all tasks, both with and without SOC f.e.

Our results echo, at a much higher resolution, what we found in Figure 1. Placing little guidance on the categorization of tasks, and using the natural language of the job ad descrip-

tions to measure tasks, this exercise reveals that non-routine and abstract tasks have the steepest positive gradient. Examples include “managing projects,” “problem-solving skills,” and “developing strategies.” Communication and group interactions are important, too, as illustrated by the gradients of “written communication” and “maintaining relationships.” The tasks with the steepest negative gradient reflect more routine activities and emphasize following directions, including “operate cash-register,” “greeting customers,” and “maintaining inventory.” Table 2 also shows the steepest positive and negative gradients with six-digit SOC fixed effects and the patterns are similar. The correlation of task rankings with and without SOC f.e. is 0.67.<sup>17</sup>

## 3.2 Technology Requirements Across Space

We next systematically explore the importance of new technologies in large CZs and study how this relationship varies with the educational requirements of jobs. Our analysis is motivated by prior work that finds cities are at the forefront of innovation (Carlino et al., 2007; Lin, 2011). We leverage the rich text data available in job postings, which allow us to observe individual technologies at the job-level and allow us to study precisely how technological adoption differs for college and non-college jobs.

We measure the technology requirements of a job by searching for each of O\*NET’s Hot Technologies. The list is originally derived from job postings and includes 180 different technologies.<sup>18</sup> Figure 3 presents a job ad-level regression of the number of technologies that are a job requirement, on CZ size deciles, controlling for log ad length. Panel I is without any occupation controls, and panel II includes six-digit SOC fixed effects. Panel I shows an increase in technological requirements with labor market size. Note that the technology gradient appears only for jobs requiring a college degree. Panel II includes six-digit SOC fixed effects. Once again, the gradient is stronger for jobs requiring a college degree.

The results in Figure 3 provide three main conclusions. First, technology intensity is a

---

<sup>17</sup>For robustness, we report the steepest positive and negative gradients with respect to a continuous measure of log population in Table B.5. In addition, we reproduce the table using verbs only, rather than verb-noun pairs, to represent tasks using the list of verbs from Michaels et al. (2018); see Table B.7. Both robustness exercises reveal a similar pattern of increased interactivity and teamwork in large CZs.

<sup>18</sup>We list the technologies in Appendix B.3; the list is also available on the O\*NET website: [https://www.onetonline.org/search/hot\\_tech/](https://www.onetonline.org/search/hot_tech/). We accessed the data August 27, 2019 and note that the O\*NET Hot Technologies are periodically updated. The initial list contains 182 technologies, but we exclude R and C from our main analysis since they are likely to lead to false positives. Appendix B.5 reproduces the main analysis including R and C and shows that the results are unchanged. We also flag and exclude false positives of social media technologies (Facebook, YouTube, and LinkedIn) in our main analysis, since these technologies are likely to be mentioned in the context of encouraging the job applicant to visit the firm’s social media page. We describe our criteria for identifying false positives of social media technologies in Appendix B.3.

dimension along which work varies greatly across labor markets: A job in population decile 10 has 0.14 more mentions of technologies relative to a job in the lowest decile, which has a mean of 0.10 mentions per ad. Second, the gap in technology intensity between college and non-college work becomes larger with labor market size.<sup>19</sup> Finally, a substantial fraction of this correlation with market size—but crucially not all—is contained in differences in occupations. The point estimate for decile 10 is 11 percent as large in Panel I as in Panel II, implying that 11 percent of the CZ size premium reflects within-occupation differences.

We next narrow our focus to study more granular measures of technology adoption, examining which technologies have the steepest positive gradient with respect to labor market size. We estimate equation (1), replacing the dependent variable with  $tech_{jn}^{(\ell)}$ , an indicator for job ad  $j$  being located in market size decile  $n$  requiring technology  $\ell$ . We run this regression for each of the 180 technologies, and sort by  $\beta_{10}^{(\ell)}$ , after normalizing the estimates by dividing by the standard deviation of  $tech_{jn}^{(\ell)}$ . The results are presented in Table 3. The technologies with the steepest positive gradient with market size are Microsoft Excel, Python, JavaScript, Microsoft Project, and Linux. Furthermore, both more established technologies, such as the Microsoft suite, and newer ones, such as Ajax and Git, are more prevalent in larger CZs. Separating the analysis by education, jobs requiring a college degree have the steepest gradients for technologies involving computer programming (e.g., Python, JavaScript, Linux), while jobs requiring a high school diploma have the steepest gradients for technologies involving data entry and word processing (e.g., the Microsoft Office suite).<sup>20</sup>

These results show that large CZs are also at the forefront of new technology adoption. Our results complement the findings in the literature that new patents and new occupational titles appear with greater frequency in cities (Carlino et al., 2007; Lin, 2011). Unlike prior work, our granular data allow us to observe technology use at the job-level, technology-by-technology. Importantly, while new technologies are adopted more intensively by workers in large CZs, we find a large education gap in technology adoption between college and non-college workers, one that widens with CZ size.<sup>21</sup> Hence, new technologies are complementary

---

<sup>19</sup>In Appendix C.1, we explore whether the gradients for tasks and technologies might be sensitive to the time period studied. Specifically, a potential concern is that a rapidly changing labor market in large v. small CZs might generate changing gradients over time. We divide the sample period into two approximately equal periods, 2012-2014 and 2015-2017, and re-estimate panel I for each time period. The broad descriptive patterns are similar across time periods.

<sup>20</sup>Table 3 omits technologies with the steepest negative gradient because the estimates are small in magnitude and only two are statistically significant at the 5 percent level. First, pooling all ads, the coefficient estimate for Swift is -0.0593 and is significantly different from 0. It is likely that for many job ads, “swift” is simply an adverb and not a reference to a technological requirement. For jobs requiring a high school diploma, no technologies have a negative gradient that are statistically significant. For jobs requiring a college degree or above, only Apache Pig has a statistically significant negative gradient (-0.0134).

<sup>21</sup>Spitz-Oener (2008) and Atalay et al. (2018) provide evidence that new technologies tend to complement

with higher levels of education, and this complementarity is stronger in large CZs.

### 3.3 Specialization in Tasks Across Space

Since Adam Smith, economists have pointed to worker specialization as a key force behind the productivity gains in large markets (Young, 1928; Stigler, 1951; Becker and Murphy, 1992). Smith noted that larger markets allow workers to specialize in narrower sets of activities and, as a result, become more productive. But specialization in tasks has eluded direct measurement.

In this section, exploiting our granular task measures, we provide a new and more detailed measure of worker specialization: the dissimilarity in tasks that workers perform relative to their peers within the same firm-market, industry-market, or occupation-market. We then demonstrate that this measure of specialization increases with market size.

To study specialization, we first need a notion of distance between jobs in task space. We characterize each job  $j$  as a vector of tasks,  $T_j$ , with each element corresponding to a distinct task. Each element takes a value of one if job ad  $j$ 's description contains the corresponding task, and zero otherwise. We normalize the task vectors to have unit length:  $V_j = \frac{T_j}{\sqrt{T_j \cdot T_j}}$ . The normalization ensures that our measures of specialization are unaffected by job ad length.

The inner product between two task vectors is their cosine similarity, which takes a value between zero and one. Intuitively, if two jobs have perfect overlap in tasks, their similarity is one, and if they have no tasks in common, their similarity is zero.<sup>22</sup> We define the task dissimilarity between job ads  $j$  and  $j'$  as one minus their cosine similarity:  $d_{jj'} = 1 - V_j \cdot V_{j'}$ .

We define specialization within a firm-market as the average task dissimilarity between job ad  $j$  and other ads in the firm-market pair. For this analysis, we denote a firm  $f$  as a firm name  $\times$  six-digit industry NAICS code.<sup>23</sup> Define  $d_{jfm} = 1 - V_{jfm} \cdot \bar{V}_{(-j)fm}$ , where  $\bar{V}_{(-j)fm}$  is the vector of average task content in firm-market  $fm$ , averaged over all ads in the firm-market excluding job ad  $j$ . If the term  $d_{jfm}$  is larger, job ad  $j$  has less overlap in task content with other ads in the firm-market  $fm$ . At the firm level, the degree of specialization

---

analytic tasks. To the extent that analytic tasks are more intensive for college workers (compared to non-college workers) we uncover here that these complementarities are stronger with CZ size. Our analysis of new technologies also contributes to this literature in that it covers the U.S. in the 21st century.

<sup>22</sup>Our specialization measure is related to work that computes occupational distances using the Dictionary of Occupational Titles or O\*NET to study earnings losses from unemployment (Poletaev and Robinson, 2008; Macaluso, 2022). The job ads data allow us to form within-firm and within-occupation measures of specialization using much higher dimensional task vectors.

<sup>23</sup>We group by both firm name and industry because the same firm name may, in certain cases, correspond to two separate firms in two different industries. Since these cases are rare, our results are essentially unchanged when grouping by firm name only.

is  $d_{fm} = \frac{1}{n_{fm}} \sum_{j \in fm} d_{jfm}$ , where  $n_{fm}$  is the number of job ads in the firm-market. We emphasize that we cannot construct dissimilarity for all workers in the firm-market but only for vacancies, which capture newly formed jobs.<sup>24</sup>

Note that we can define task dissimilarity more generally,  $d_{jcm} = 1 - V_{jcm} \cdot \bar{V}_{(-j)cm}$ , where  $c$  may represent job ad  $j$ 's firm or its occupation. In our analysis we explore dissimilarity along these two dimensions. We estimate the following regression:

$$d_{cm} = \alpha_0 + \sum_{n=2}^{10} D_{mn} \alpha_n + x'_{cm} \delta + \epsilon_{cm}, \quad (2)$$

where  $d_{cm}$  is the mean task dissimilarity in group  $c$  and market  $m$  (where  $c$  refers to either firm or occupation),  $D_{mn}$  is an indicator that market  $m$  is in size decile  $n$ , and  $x_{cm}$  are our main controls averaged to the group-market cell. In specifications in which  $c$  refers to occupation,  $x_{cm}$  may also include occupation fixed effects.<sup>25</sup>

Figure 4 plots the estimates for  $\alpha_n$ . The main result in panels I and II is that task dissimilarity within firms is increasing in market size, with a steeper gradient for nontradable sector firms. This result aligns with the classic theoretical point that the degree of specialization is limited by the extent of the market. Since the market for tradable sector firms extends beyond their CZs, the gradient of specialization with respect to local market size will be flatter for workers in these sectors. Panels III and IV show that specialization within occupations is also increasing in market size.

We perform several checks on the measurement of worker specialization and reexamine the gradient. First, we note that some tasks are intuitively similar, such as “provide feedback” and “provide recommendations.” We check the sensitivity to aggregating tasks with similar meaning, using a modeling approach from natural language processing to aggregate tasks (see Appendix C.2), and show the results are nearly identical. Within the same appendix, we apply three exercises to investigate whether the sampling of job postings may lead to measurement error in specialization measures, since small markets may have fewer job ads in an occupation-market or firm-market cell.<sup>26</sup>

---

<sup>24</sup>In constructing the firm-market sample, we drop ads that contain zero tasks—approximately 15 percent of ads—and ads that are singletons in the firm-market cell, another 4 percent. In constructing the occupation-market sample, the respective numbers are 17 percent and 0.11 percent. The average number of job ads in a firm-market cell is 8.3, and the median is 5.

<sup>25</sup>In our analysis of specialization within occupations, we use four-digit (rather than six-digit) SOCs as our unit of analysis, to have more job ads in cells with which to calculate task dissimilarity.

<sup>26</sup>First, we confirm that the patterns in Figure 4 are robust to controlling for the number of ads in the cell (Figure C.11). Second, we reproduce Figure 4, panel A, for firm-markets with above the median number of postings and for those with below the median number of postings (Figure C.12). The results for the two groups look quite similar. Third, we do a placebo-type analysis of national chains and show that these chains

So far, we have demonstrated that workers are more specialized, within their firm or occupation, in larger markets. The same is true for firms: The distance in task space among firms within the same (six-digit NAICS) industry increases in market size. To see this, first define the dissimilarity between firm  $f$  in industry  $i$  and market  $m$  and other firms in the industry-market as  $d_{fim} = 1 - \bar{V}_{fim} \cdot \bar{V}_{(-f)im}$ . In this equation,  $\bar{V}_{fim}$  is the vector of average tasks for the firm-industry-market, and  $\bar{V}_{(-f)im}$  is the vector of average tasks for all firms other than  $f$  in the industry-market. For each industry-market pair, the average across-firm specialization is  $d_{im} = \frac{1}{n_{im}} \sum_{f,m} d_{fim}$ ; here  $n_{im}$  is the number of firms in industry  $i$  and market  $m$ .

We compare market size and between-firm specialization using the following regression:

$$d_{im} = \alpha_0 + \sum_{n=2}^{10} D_{mn} \alpha_n + x'_{im} \delta + \epsilon_{im}. \quad (3)$$

Here,  $d_{im}$  is the mean task dissimilarity in industry  $i$  and market  $m$ ,  $D_{mn}$  is an indicator that market  $m$  is in size decile  $n$ , and  $x_{im}$  includes controls for the average (log) length among ads posted by industry  $i$  firms in market  $m$ . In certain specifications,  $x_{im}$  also includes industry fixed effects. These industry-market regressions are weighted by the number of firms in the cell.

Figure 5 presents our estimates of equation (3). The main takeaway is that firms are located further apart in task space in larger markets, especially so for firms in nontradable industries.

All of these results together reveal that, as market size grows, there is an increase in both within- and between-firm specialization in tasks. Our approach to measuring specialization has several advantages. It is comprehensive, in that it characterizes the universe of job postings, while simultaneously providing fine measures of specialization. Thus, we go beyond case studies that have provided detailed analyses of specific occupations, such as doctors (Baumgardner, 1988) and lawyers (Garicano and Hubbard, 2009). We also complement the literature that measures specialization as occupational diversity (Bacolod et al., 2009b; Duranton and Jayet, 2011; Tian, 2019) in that we construct specialization measures based directly on job tasks and are thus able to speak about specialization in tasks themselves.<sup>27</sup>

---

have a flattened specialization gradient, as we might expect given the relative homogeneous organizational structure of national chains across space (see Figure C.13).

<sup>27</sup>In Appendix C.2., we reproduce the findings of this literature. We document that occupations that are rare as a share of the entire U.S. labor market make up a greater share of larger markets relative to smaller markets, replicating Duranton and Jayet's (2011) analysis of French labor markets. We also reproduce the finding of Tian (2019) in the U.S. context, showing that, conditional on the number of ads posted by the firm, there are more distinct job titles per firm in larger markets.

As we show in Section 3.5, all of these differences have implications for wages.

### 3.4 Elasticities with Respect to Log Population

Our main figures present the intensity of tasks, technologies, and the degree of specialization with market size deciles. Researchers may be interested in a single number that summarizes the elasticity of each of these outcomes with respect to log population. In this section, we adopt a second, complementary, empirical approach to present elasticities of tasks with respect to a continuous measure of log population, following a two-step procedure ([Combes and Gobillon, 2015](#)).

The first step is an ad-level regression of task intensity  $t_{jn}^{(k)}$  (or technology intensity, or the degree of specialization) on controls (ad length and, where indicated, six-digit SOC fixed effects) and CZ indicators. In the second step, we regress the CZ effects on log CZ population, weighted by the number of ads in the cell. We report the slope estimate in the second step along with the standard error (in parentheses) in Table 4. Most elasticities diminish with the inclusion of occupation fixed effects, but important differences remain: about 29 percent of the elasticity for non-routine interactive tasks remains with SOC fixed effects, and about 15 percent of the elasticity for non-routine analytic tasks remains. The elasticity for occupation-market specialization does not diminish with SOC fixed effects.

### 3.5 Tasks, Technologies, and Wages

In previous sections, we have documented that interactive tasks, technology usage, and worker specialization all increase with CZ size.<sup>28</sup> In this section, we demonstrate that earnings are positively associated with these three factors, and, as a result, help explain differences in earnings observed between large and small CZs.

We compute the mean task dissimilarity within each occupation-CZ pair,

$$d_{om} = \frac{1}{n_{om}} \sum_{j \in om} (1 - V_{jom} \cdot \bar{V}_{(-j)om}),$$

the mean number of technological requirements at the occupation-CZ,  $tech_{om}$ , and, using our ACS sample, the fraction of employed workers in the occupation-CZ with a BA or above,  $ba_{om}$ .

We run the following regression:

---

<sup>28</sup>We have also documented that analytic tasks increase with CZ size. In what follows, we only focus on three key channels—interactive tasks, technologies, and specialization—motivated by the theories we have discussed earlier in the paper and to have a parsimonious accounting of the wage premium.

$$\log(wage)_{om} = \gamma_0 + \gamma_1 t_{om} + \gamma_2 tech_{om} + \gamma_3 d_{om} + \gamma_4 ba_{om} + \xi_o + \epsilon_{om}. \quad (4)$$

We include four-digit occupation fixed effects,  $\xi_o$ , in some specifications of equation (4) to highlight the role of tasks and technologies in accounting for within-occupation wage differences across markets. In equation (4),  $t_{om}$  is the occupation-market sum of internal and external interactive tasks, normalized to have mean zero and standard deviation one across jobs.<sup>29</sup>

One should be cautious in interpreting the  $\gamma$  coefficients as causal, since, for example, workers may sort endogenously into occupations by unobservables in local labor markets that may correlate with wages. Nevertheless, it is valuable to assess whether within-occupation differences in tasks and technologies account for variation in wages across geography, beyond what is captured by differences in worker skills or occupation categories, and  $\gamma_1$ ,  $\gamma_2$ , and  $\gamma_3$  are key parameters for doing so. To the extent that these parameters are statistically and economically significant, they convey suggestive evidence that job tasks and technologies are a mechanism behind the large CZ premium. In addition, they demonstrate the value of using job ad text to measure job characteristics beyond occupational categories.

Table 5 reports the results. Column 1 shows that a one-standard-deviation increase in interactive tasks is associated with an increase in wages by approximately 12.3 percent, while a 0.1 increase in the number of technology mentions increases wages by 3.9 percent. A one-standard-deviation increase in task dissimilarity is associated with an increase in wages by 3.3 percent. Adding SOC fixed effects in column 2 weakens the coefficients on interactive tasks and technologies, but these estimates remain economically and statistically significant. Column 3, which controls for education, shows that measures of interactive tasks, technologies, and specialization account for variation in wages above occupational categories and worker education. This result emphasizes the importance of measurement within occupational categories for understanding wage inequality across geography.

Columns 4-7 re-estimate equation (4) separately by occupational category. We classify workers into white-collar and blue-collar workers by two-digit SOC, as described in the table note.<sup>30</sup> Within-occupation differences in interactive tasks plays an important role in ac-

---

<sup>29</sup>Our preferred specification of equation (4) excludes CZ fixed effects, since our aim is to account for differences in wages across CZs of different sizes, an exercise that the inclusion of CZ fixed effects would preclude. Furthermore, Smith's theory of specialization predicts that it is through market size that the productivity gains of specialization are realized. Nevertheless, Appendix C.3 presents the results with CZ fixed effects, showing that, consistent with this theory, the relationship between specialization and wages is diminished, although it remains significant for white-collar occupations. Technology intensity remains significantly positively related to occupation-CZ wages.

<sup>30</sup>We analyze white- and blue-collar occupations to study two occupation groups that have, respectively, higher-educated and lower-educated workers. We require subgroups at the occupation level (and not ac-

counting for the wage premium, particularly for white-collar occupations. Similarly, columns 4-7 show that white-collar workers have a within-occupation premium for technological requirements, while blue-collar workers do not. Lastly, note that within occupation-CZ task dissimilarity is associated with a wage premium for white-collar occupations, but much less so for blue-collar occupations.<sup>31</sup>

We use these coefficient estimates to gauge the importance of interactive tasks, technologies, and worker specialization in accounting for the market size premium. After controlling for occupation fixed effects, workers in the 10th population decile have wages that are 30.1 log points higher than those in the bottom decile. The intensity of the interactive task measure, aggregating internal and external interactions, is approximately 0.16 standard deviations higher in top decile CZs relative to bottom decile CZs. Hence, column 2 of Table 5 indicates that interactive tasks account for 0.54 ( $\approx 0.16 \cdot 0.034$ ) log points of the within-occupation difference in wages for workers living in top and bottom population deciles. As panel IV of Figure 4 indicates, specialization in top decile CZs is 1.28 standard deviations greater than in bottom decile CZs. Thus, column 2 of Table 5 reveals that our specialization measure accounts for 4.6 ( $\approx 1.28 \cdot 0.036$ ) log points of the difference in wages for workers living in top and bottom population deciles. The technology measures account for an additional 1.02 ( $\approx 0.03 \cdot 0.340$ ) log points, where the 0.03 comes from the estimate reported in Figure 3, panel II. Together, the three variables account for 21 percent ( $\approx 6.2/30.1$ ) of the CZ size-wage premium. Furthermore, using the coefficient estimates from column 4, the three measures account for 22.8 percent (9.3 log points) of the 40.8 log point CZ size-wage premium in white-collar occupations.<sup>32</sup> In sum, our interactive tasks, technologies, and specialization measures account for a substantial portion of the CZ size-wage premium as well as the steeper CZ size-wage premium for highly skilled workers that exists within occupations.<sup>33</sup>

---

cording to education) for this analysis, since specialization measures are defined at the occupation-market level.

<sup>31</sup>These regressions rely on wage data from the ACS. Wages are available in a subsample of job ads in the Burning Glass data. We discuss the selection of job ads with posted wages in Appendix C.5. We reproduce Table 5 using wage data from Burning Glass in Appendix Table C.12 and find estimates that are surprisingly similar in magnitude, despite potential selection concerns.

<sup>32</sup>We make this calculation as follows: Between top and bottom population deciles, the white-collar interactive task gap is 0.21 standard deviations, the technology gap is 0.04 mentions, the task dissimilarity gap is 1.06 standard deviations, and the wage gap is 40.8 log points. Using the estimates from Table 5, the three components account for  $(0.21 \cdot 0.054 + 0.04 \cdot 0.367 + 1.06 \cdot 0.063)/0.408 \approx 22.8\%$  of the wage gap between bottom and top population decile CZs.

<sup>33</sup>If we perform the analogous calculation conditional on the worker having a BA or above and the corresponding conditional estimates from Table 5 (columns 3 and 5), we obtain that interactive tasks, technologies, and specialization measures account for 18.7 percent of the 24.4 log point conditional CZ size-wage premium, and 19.3 percent of the 32.8 log point conditional CZ size-wage premium for white-collar workers.

## 4 Interpretation of Our Results

Our main result is that jobs are fundamentally different in large CZs. They involve more human-to-human interaction, greater use of information and communication technologies, and increased worker specialization. Moreover, the differences in work practices that we document are more pronounced for higher-educated workers, and their association with wages are larger for higher-skilled, white-collar occupations. Our data allow us to document these findings with a degree of granularity that was not previously possible. In this section, we discuss how our understanding of the sources of the CZ size-wage premium is enriched by these new facts and our new approach to task measurement.

An ongoing debate in the labor literature is whether the market size premium is due largely to the sorting of workers ([Card et al., 2021](#)) or the productivity benefits of workers' locations ([De la Roca and Puga, 2017](#)), with significant implications for the effectiveness of place-based v. worker-based policies ([Kline and Moretti, 2014](#)). A key limitation of existing research is that even the best administrative datasets in the U.S., such as the Longitudinal Employer-Household Dynamics program used in [Card et al. \(2021\)](#), lack information on the content of work activities. Our paper adds to this debate: Jobs themselves differ, and the CZ size-wage premium is not just a reflection of worker unobservables. To the extent that the selection of workers is important—e.g., workers with communication skills or greater facility with new technologies may sort into large CZs—our paper provides evidence that this sorting is a response to demand.<sup>34</sup> One implication of this finding is that the migration of workers is likely limited by the differing work activities demanded across space.

In addition to informing the sources of the CZ size-wage premium, our findings inform why workers of different skill levels have different CZ size premia. There is limited evidence on the mechanisms behind the college-non-college gap in the CZ size premium, because existing data sources do not allow researchers to comprehensively measure the content of jobs separately by worker education level. We document that the college-non-college gap is due in part to differences in interactive tasks, the use of new technologies, and worker specialization. We show that while college workers have a positive gradient for interactive tasks and the adoption of new technologies, these gradients are flat for non-college workers. In addition, our wage regressions show that these three mechanisms are far more important for white-collar occupations than for blue-collar occupations.

Lastly, our results provide the most direct empirical evidence to date that the degree of worker specialization increases with market size and is an important component of the CZ

---

<sup>34</sup>While employers undoubtedly respond to supply conditions, and the job description content may reflect these conditions, the fact that employers explicitly mention interactive tasks and technologies suggests that employers demand these types of workers.

size-wage premium. While specialization, and its significance as a mechanism for productivity gains, is one of the oldest theoretical ideas in economics, direct measurement of specialization has been elusive due to the limitations of existing data sources. The state-of-the-art method is to count the number of distinct, or rare, occupations in a market without directly utilizing information on the sets of tasks that workers perform ([Duranton and Jayet, 2011](#); [Tian, 2019](#)). Hence, prior research does not capture the relationship within or between occupations, which may have more or less overlap in tasks. In addition, our approach allows us to measure within- and between-firm specialization using a common methodology, and has applications beyond the CZ size premium. Our empirical evidence shows that both coordination within firms and worker specialization rise together with market size, lending empirical support to the theoretical insight of [Becker and Murphy \(1992\)](#).

## 5 Conclusion

By applying tools from natural language processing to rich textual data from online job ads, we examine in detail the differential task and technology content of jobs between large and small commuting zones. We also introduce an approach to define job tasks at a granular level. With our granular task measures, we characterize the relation between market size and specialization—a key driver of productivity that has eluded direct measurement. We have shown that the task content of occupations is critical to understand why average wages and the skill premium rise with CZ size. We believe, moreover, that the application of the type of fine-grained analysis we develop in this paper can shed light on a large set of economic phenomena, ranging from the limits to human capital mobility across regions to the design of policies aimed at enhancing labor market fluidity.

# Figures and Tables

Figure 1: Tasks and Market Size

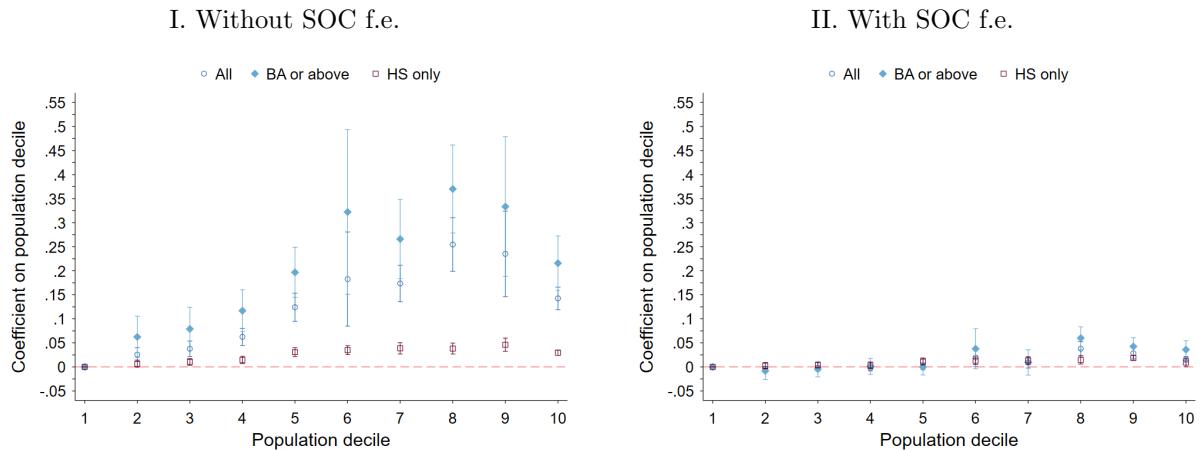

This figure presents estimates of equation (1). We control for log total ad words and, in the right panels, six-digit SOC fixed effects. The dependent variable is task intensity. Standard errors are clustered at the CZ level.

Figure 2: O\*NET Interactive Tasks Gradient

This figure presents estimates of equation (1). We control for log total ad words and, in the right panel, six-digit SOC fixed effects. The dependent variable is task intensity. Standard errors are clustered at the CZ level.

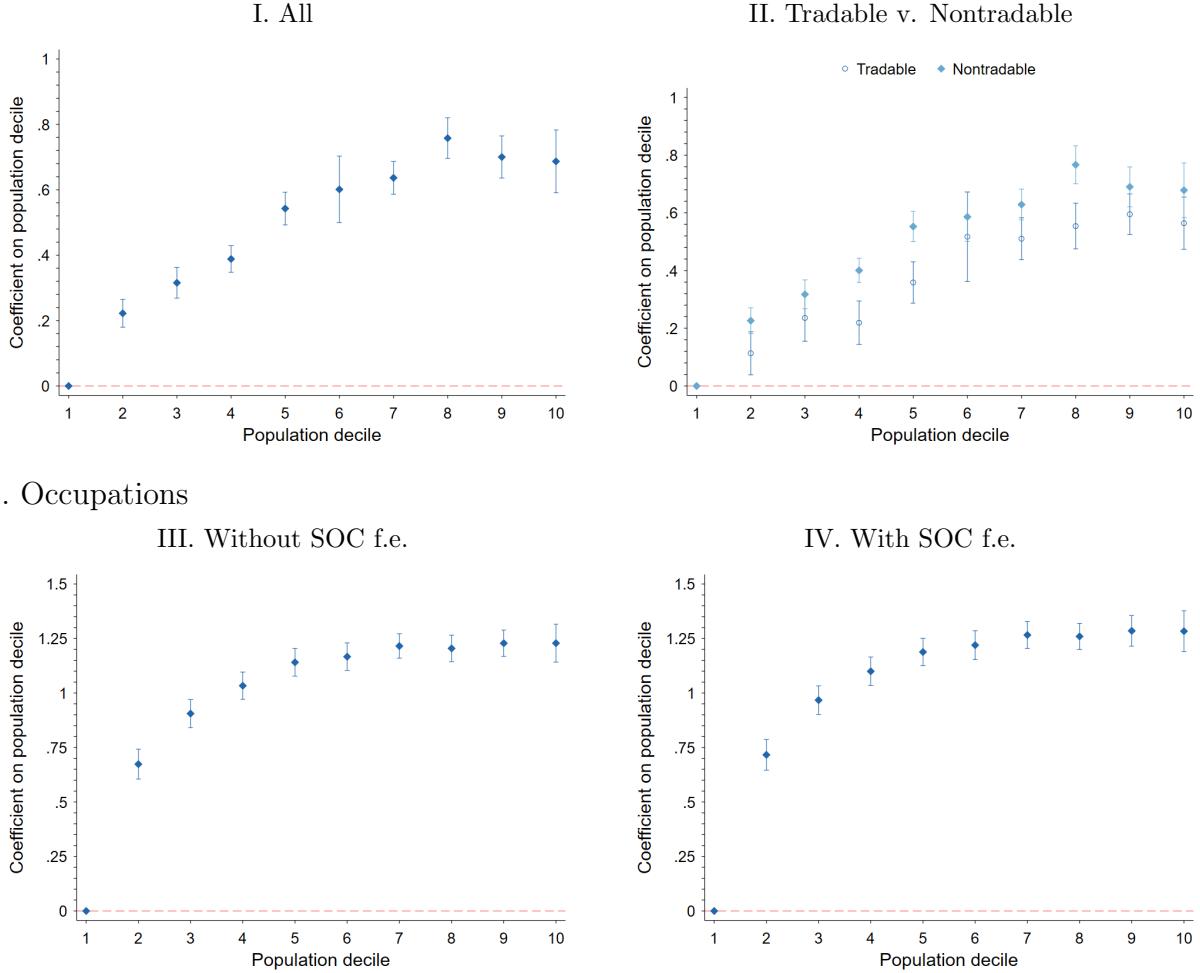

Figure 3: The Technology Gradient

The dependent variable is the number of O\*NET Hot Technologies mentioned in the ad, which is regressed on a vector of deciles for CZ size. For reference, the 1st population decile mean is 0.10 across all job ads, 0.26 for BA or above, and 0.08 for HS only. We control for log total ad words. Panel II includes six-digit SOC fixed effects. Standard errors are clustered at the CZ level.

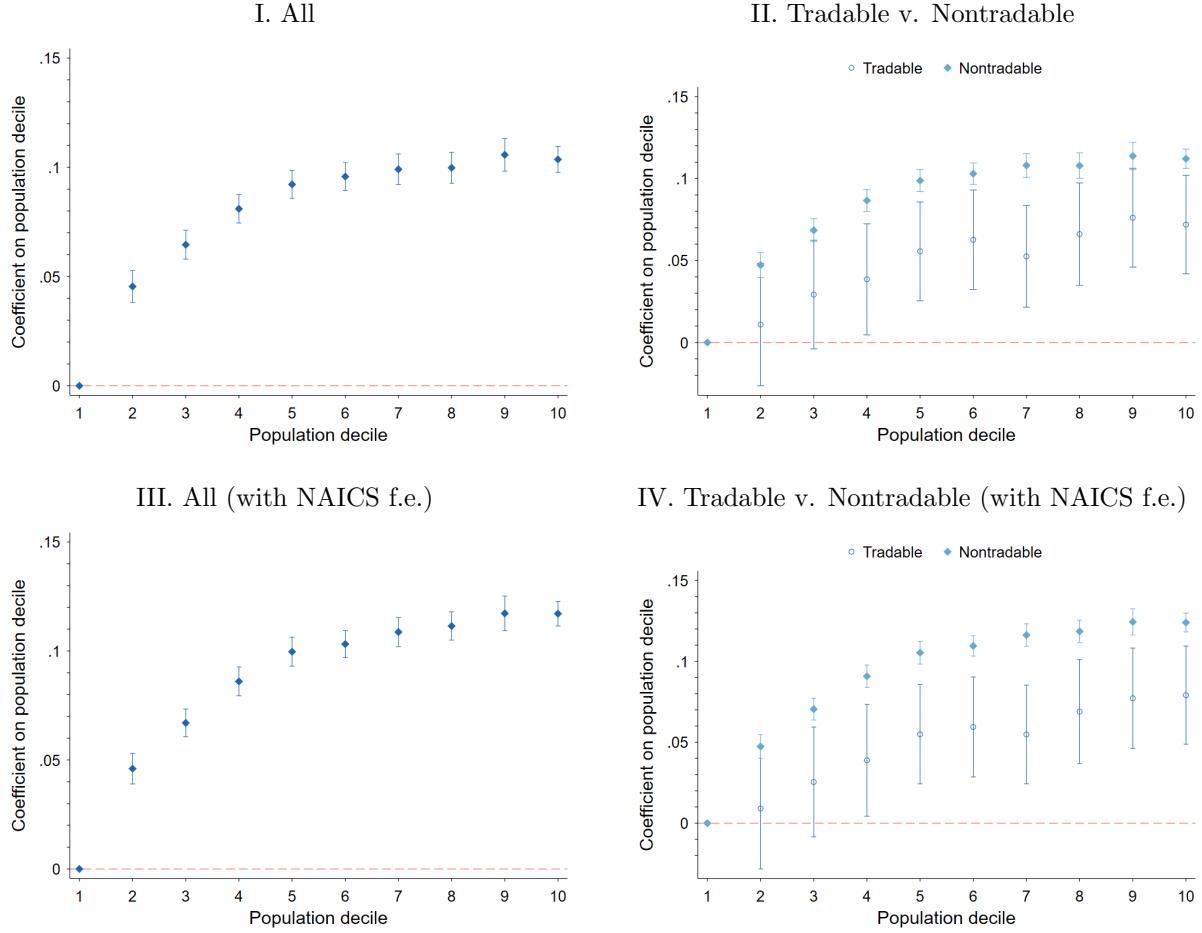

Figure 4: Specialization Gradient: Task Dissimilarity Within Firms and Occupations

### A. Firms

The figure presents estimates of equation (2) and studies how task dissimilarity within the firm (panel A) and within the occupation (panel B) vary with market size. Panel A uses the firm-market sample, and the dependent variable is the mean task dissimilarity in the firm-market, while panel B uses the occupation-market sample, and the dependent variable is mean task dissimilarity in the occupation-market. We control for log total ad words, which is averaged to the cell level. Firm-market regressions are weighted by number of ads in the cell; occupation-market regressions are weighted by ACS employment in the cell. Standard errors are clustered at the CZ level. For reference, the 1st population decile mean for the top left panel is -0.51, and for the top right panel is -0.54 for the nontradable sample and -0.03 for the tradable sample. The 1st population decile mean for the bottom two panels is -1.92. We define tradable by two-digit NAICS code: agriculture, forestry, fishing and hunting (11), mining, quarrying, and oil and gas extraction (21), and manufacturing (31-33).

Figure 5: Specialization Gradient: Task Dissimilarity Across Firms

The figure presents estimates of equation (3). The panels above use the industry-market sample, and the dependent variable is the mean task dissimilarity in the industry-market. We control for log total ad words, which is averaged to the cell level. The industry-market regressions are weighted by number of firms in the cell. Standard errors are clustered at the CZ level.

Table 1: Most Common Tasks for Selected Occupations

	Electricians		Supervisors of Retail Sales		Registered Nurses		Lawyers	
Rank	Task	Mean	Task	Mean	Task	Mean	Task	Mean
1	use hands	0.1230	provide customer_service	0.2973	providing care	0.1564	written communication	0.1497
2	build relationships	0.0990	assist store	0.2082	continuing education	0.0858	providing support	0.0928
3	written communication	0.0940	written communication	0.1643	written communication	0.0682	working team	0.0665
4	ensure compliance	0.0933	ensure stores	0.1483	provides quality	0.0597	meet requirements	0.0580
5	perform maintenance	0.0787	maintain store	0.1435	demonstrate knowledge	0.0462	provide service	0.0517
6	lift lbs	0.0571	driving sales	0.1269	working team	0.0411	writing skills	0.0463
7	work shift	0.0518	closes store	0.1258	provide service	0.0408	provide guidance	0.0451
8	preferred ability	0.0429	assisting customers	0.1251	develop planning	0.0393	ensure compliance	0.0417
9	lifting pounds	0.0417	maintaining inventory	0.1243	establish policies	0.0358	conducting research	0.0365
10	provides leadership	0.0383	lifting pounds	0.1048	making decisions	0.0338	meet deadlines	0.0306
N		8,073		320,882		241,859		14,400

The table above lists the most common verb-noun pairs, and their mean frequency per ad, for each of four occupations: Electricians (47-2111), Supervisors of Retail Sales (41-1011), Registered Nurses (29-1141), and Lawyers (23-1011). The number of job ads for each occupation is reported in the bottom row.

Table 2: Tasks with the Steepest Gradient: Extracting Tasks Directly from Ads

Positive Gradient				Negative gradient			
No SOC f.e.		SOC f.e.		No SOC f.e.		SOC f.e.	
Task	$\hat{\beta}_{10}$	Task	$\hat{\beta}_{10}$	Task	$\hat{\beta}_{10}$	Task	$\hat{\beta}_{10}$
written communication	0.1596	achieving sales	0.0701	maintain store	-0.1763	maximizes profitability	-0.1597
managing projects	0.1157	ensure safety	0.0686	maximizes profitability	-0.1692	protect company	-0.1501
meet deadlines	0.1075	written skills	0.0580	operating cash_register	-0.1653	maintain store	-0.1339
providing support	0.0956	stand walk	0.0573	protect company	-0.1641	operating cash_register	-0.1256
maintaining relationships	0.0943	driving sales	0.0572	make changes	-0.1431	make changes	-0.1249
written skills	0.0922	exceed sales	0.0556	provide customer_service	-0.1394	greeting customers	-0.1094
problem_solving skills	0.0881	providing environment	0.0523	preventing trafficking	-0.1373	procedures cash	-0.1080
working relationships	0.0844	providing coaching	0.0510	greeting customers	-0.1343	skating carhop	-0.1064
develop business	0.0833	according company	0.0500	skating carhop	-0.1334	ensure employees	-0.1041
developing strategies	0.0754	prioritize tasks	0.0500	procedures cash	-0.1264	unloading trucks	-0.1005
identify opportunities	0.0751	working relationships	0.0488	maintaining inventory	-0.1234	drive_in employees	-0.0981
prioritize tasks	0.0739	handle tasks	0.0487	assist store	-0.1221	maintaining inventory	-0.0948
develop relationship	0.0728	using eye	0.0461	unloading trucks	-0.1191	assigned store	-0.0873
make recommendations	0.0724	including nights	0.0449	ensure employees	-0.1143	working store	-0.0852
support business	0.0721	meet sales	0.0448	drive_in employees	-0.1104	provide customer_service	-0.0848

We estimate equation (1) separately for each task, without any controls, and again with six-digit SOC f.e. We normalize the estimates by dividing by the standard deviation of the task. The table above presents the tasks with the steepest positive and negative gradients with respect to market size, as captured by  $\hat{\beta}_{10}$ , which reflects the difference between 10th and 1st decile market size. All coefficients are statistically significant at the 1 percent level. The correlation between the task rankings, with and without SOC f.e. is 0.67.

Table 3: Technologies with the Steepest Gradient

All		College		High School	
Technology	$\hat{\beta}_{10}$	Technology	$\hat{\beta}_{10}$	Technology	$\hat{\beta}_{10}$
Microsoft Excel	0.1131	Geographic Information System (GIS)	0.1036	Microsoft Excel	0.0721
Python	0.0843	Python	0.0980	Microsoft Outlook	0.0527
JavaScript	0.0837	Microsoft Excel	0.0889	Microsoft Word	0.0453
Microsoft Project	0.0789	JavaScript	0.0844	Microsoft Office	0.0412
Linux	0.0785	SAS	0.0710	React	0.0277
Microsoft Word	0.0751	Linux	0.0708	Microsoft Access	0.0250
Microsoft Office	0.0720	Microsoft Project	0.0706	Microsoft Powerpoint	0.0239
SAP	0.0686	Microsoft Access	0.0650	Tax Software	0.0224
Microsoft Access	0.0685	Git	0.0644	Objective C	0.0216
Microsoft Powerpoint	0.0680	Microsoft Powerpoint	0.0597	YouTube	0.0214
Microsoft Outlook	0.0630	MySQL	0.0591	Facebook	0.0210
MySQL	0.0595	Tax Software	0.0553	Swift	0.0186
Unix	0.0589	Microsoft Office	0.0550	Python	0.0179
SAS	0.0584	Unix	0.0549	Epic Systems	0.0170
Geographic Information System (GIS)	0.0579	C++	0.0546	Ajax	0.0170

We estimate equation (1) where the dependent variable is a specific technology requirement, excluding controls. We estimate this regression separately for each O\*NET technology. All coefficients are normalized by dividing by the standard deviation of the technology. We report the technologies with the steepest positive gradient with respect to market size,  $\hat{\beta}_{10}$ , which reflects the 10th decile technology intensity relative to the 1st decile. All estimates are statistically significant at the 5 percent level, with the following exceptions in the High School column: React ( $p = 0.48$ ) and Ajax ( $p = 0.09$ ).

Table 4: Coefficients with Respect to Log Population

	All		BA or above		HS only	
	No SOC f.e.	SOC f.e.	No SOC f.e.	SOC f.e.	No SOC f.e.	SOC f.e.

Technologies	0.053 (0.002)	0.008 (0.001)	0.076 (0.004)	0.013 (0.001)	0.010 (0.001)	0.004 (0.000)
Specialization (SOC-CZ)	0.236 (0.006)	0.245 (0.007)				
	Non-Tradable	Tradable				
Specialization (Firm-CZ)	0.174 (0.004)	0.164 (0.007)				

This table presents elasticities of tasks, technologies, and the degree of specialization with respect to log population. We adopt a two-step procedure, in which the first step is an ad-level regression of task intensity  $t_{jn}^{(k)}$  (or technology intensity, or the degree of specialization) on controls (ad length and, where indicated, six-digit SOC fixed effects) and CZ indicators. In the second step, we regress the CZ fixed effects on log CZ population, weighting by the number of job ads in the CZ. We report the slope estimate in the second step along with the standard error (in parentheses). Each coefficient is a separate regression.

Table 5: Task Dissimilarity, Technologies, Interactive Tasks, and Wages

	All			White-collar		Blue-collar	
	(1)	(2)	(3)	(4)	(5)	(6)	(7)
Interactive tasks	0.123*** (0.007)	0.034*** (0.007)	0.021*** (0.005)	0.053*** (0.011)	0.028*** (0.007)	0.027*** (0.007)	0.024*** (0.006)
Technology requirements	0.385*** (0.013)	0.340*** (0.042)	0.212*** (0.026)	0.367*** (0.047)	0.214*** (0.029)	0.001 (0.029)	-0.004 (0.028)
Task dissimilarity	0.033*** (0.003)	0.036*** (0.003)	0.029*** (0.002)	0.062*** (0.006)	0.047*** (0.004)	0.007** (0.003)	0.006* (0.003)
BA or above				0.859*** (0.069)		0.933*** (0.077)	0.474*** (0.059)
SOC f.e.	No	Yes	Yes	Yes	Yes	Yes	Yes
Number of observations	44,956	44,956	44,956	24,370	24,370	11,247	11,247
$R^2$	0.240	0.811	0.840	0.768	0.819	0.568	0.580
Mean of dependent var.	10.784	10.784	10.784	10.983	10.983	10.576	10.576
Mean task dissimilarity	0.000	0.000	0.000	0.152	0.152	-0.178	-0.178
Mean technology requirements	0.157	0.157	0.157	0.223	0.223	0.043	0.043
Mean interactive tasks	0.000	0.000	0.000	0.435	0.435	-0.915	-0.915
Mean BA or above	0.363	0.363	0.363	0.517	0.517	0.076	0.076

The unit of observation is the occupation-market. The dependent variable is log wages, regressed on the sum of external and internal tasks (normalized to have mean zero and standard deviation one across jobs), mean number of technologies, occupation-market task dissimilarity (normalized to have mean zero and standard deviation one across jobs), the fraction of workers with a BA or above, a control for log total ad words, and, where indicated, four-digit SOC fixed effects. Regressions are weighted by employment. Standard errors are clustered at the CZ level. Occupations are classified into blue-collar and white-collar by two-digit SOC as follows. Blue-collar: farming, fishing and forestry (45); construction and extraction (47); installation, maintenance and repair (49); production (51); and transportation and material moving (53). White-collar: management, business and finance (11–13); professional (15–29); sales (41); and office and administrative support (43). \*\*\* indicates a p-value less than 1%, \*\* a p-value between 1% and 5%, and \* a p-value between 5% and 10%.

## A Validating the Online Job Ads Data

This section presents supplementary information and validation of the job ads data. Appendix A.1 provides summary statistics on the CZ deciles. Appendix A.2 provides details on the construction and cleaning of the sample used in the paper. Appendix A.3 discusses the representativeness of online vacancies relative to total vacancies as measured in JOLTS. In Appendix A.4, we show that the education requirements in the job ads data correlate strongly with the education of employed workers in the ACS in the same occupation-market, and that this relationship holds across large and small markets and within and between occupations. In Appendix A.5, we show that when we create occupation-level task measures from the job ad text that correspond to O\*NET task categories, these measures are highly correlated with O\*NET importance scales. Furthermore, drawing on a survey conducted as part of the Princeton Data Improvement Initiative, we validate our ad-based task measures using within-occupation variation. In Appendix A.6, we show that while there are trends in job ad length across space—larger markets have longer job ads—once we control for ad length, the gradient of job description keywords with respect to market size becomes economically insignificant.

### A.1 CZ Decile Summary Statistics

There are 722 CZs in our analysis sample. Table A.1 presents summary statistics by CZ decile, including the total number of job ads in the decile, the median CZ population, and the name(s) of the median population CZ(s) within the decile. CZs are assigned to market size deciles using employment weights so that each decile  $n$  has approximately the same number of employed workers. Note that Table A.1 shows that the number of job ads in each decile differs somewhat due to the discreteness of assigning each CZ to one decile.

Table A.1: CZ Decile Summary Statistics

Decile	Total ads	Pct. urban	Density	Median CZ pop.	Median CZ name(s)
1	506.8	42.2	16.9	54.9	Norfolk & Madison Counties, NE
2	575.0	67.3	72.9	304.7	Jackson & Hillsdale & Lenawee Counties, MI; Bloomington, IN
3	595.2	76.6	132.7	609.6	Wichita, KS
4	599.8	83.9	202.3	1,033.4	Tulsa, OK; Naples-Marco Island, FL
5	732.3	88.7	426.8	1,639.0	Nashville-Davidson-Murfreesboro, TN
6	692.3	92.1	440.8	2,441.2	St. Louis, MO
7	705.1	94.9	461.1	3,453.2	Minneapolis-St. Paul, MN; Hartford-Bridgeport-Stamford-Norwalk, CT
8	858.4	96.0	666.5	5,056.6	Atlanta, GA
9	685.3	96.6	1,103.4	6,159.5	Newark-Trenton-White Plains NJ-NY; Houston, TX
10	385.4	98.5	920.7	15,273.6	New York, NY; Los Angeles, CA

The table above presents summary statistics by CZ decile, including the total number of job ads in the decile (expressed in 1,000s), the mean fraction of the population that is urban, the mean population density (persons per square kilometer), the median CZ population in the decile (in 1,000s), and the name(s) of the median population CZ(s) within the decile. In cases in which the median CZ population is the average of two CZs, we provide both names. Area and percent urban are provided by the U.S. Census's 2010 Percent Urban and Rural by County report, which we link to CZ and then report mean CZ statistics in the decile.

## A.2 Details on Sample Construction

We use a 5 percent sample of the online job ads data we purchased from EMSI. The sample of our dataset covers January 2012 to March 2017. We exclude ads with fewer than the 1st percentile number of words and greater than the 95th percentile number of words. These restrictions ensure that the ads have enough content to measure tasks and also are not so long as to considerably slow processing time. This step limits the sample to ads with length between 11 and 841 words and reduces the sample to 7.0 million ads. We exclude Hawaii and Alaska from the analysis, which drops another 35,529 ads. We also exclude ads that do not contain a county FIPS code, and therefore cannot be mapped to a CZ. This step drops another 503,051 ads. Finally, we drop ads that have no SOC code—another 102,154 ads. This leaves 6.3 million ads for our occupational analysis. Table A.2 presents the number of ads by year in the sample.

For the firm-level analysis sample, we impose a few additional restrictions. We drop ads placed by staffing or placement agencies, since they act as intermediaries between the worker and the firm hiring the worker. These ads are identified with a flag in the EMSI data. This step drops 596,578 ads. (We discuss ads placed by staffing agencies in the next paragraph.) We drop ads without a firm name, which is another 107,317 ads. Finally, we drop firms with no NAICS code—another 3,771 ads. These restrictions yield approximately 5.6 million ads for the sample used for the firm-level analysis.

Jobs are more likely to be posted by a staffing agency in larger markets. This gradient

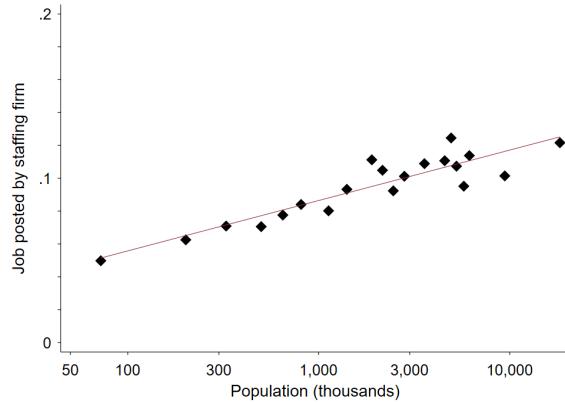

can be seen in Figure A.1, which presents a binscatter of an indicator for the job ad's being posted by a staffing firm against the CZ population. To better understand these types of ads, we estimate a job ad-level regression of an indicator for a BA-requirement (or a HS-only requirement) on an indicator for the job being posted by a staffing agency, and estimate this regression for the sample of jobs with a non-missing education requirement. These results are reported in Table A.3. The main takeaway is a job ad posted by a staffing firm, on average, has an 19 percentage point higher likelihood of requiring a BA, which is mainly driven by occupational composition. Controlling for six-digit occupation fixed effects, the estimate is 4.4 percentage points. In our analysis, we find that higher-skilled jobs are more specialized; hence, the greater composition of staffing firm-posted vacancies in larger CZs is likely to lead us to underestimate the specialization gradient. We check the sensitivity of our specialization results by reproducing Figure 4, panel A and including the staffing firms; these results are in Figure A.2. The main takeaway that within-firm specialization is increasing in market size is unchanged.

Table A.2: Job Vacancy Counts by Year

Occupation-level dataset		Firm-level dataset	
Year	Count	Year	Count
2012	591,682	2012	504,618
2013	860,961	2013	751,387
2014	1,021,805	2014	904,882
2015	1,465,475	2015	1,327,579
2016	1,905,368	2016	1,709,801
2017	490,287	2017	429,645
Total	6,335,578	Total	5,627,912

The table above presents the number of job ads by year after applying the sample restrictions described in Appendix A.2.

Figure A.1: Job Posted by a Staffing Firm

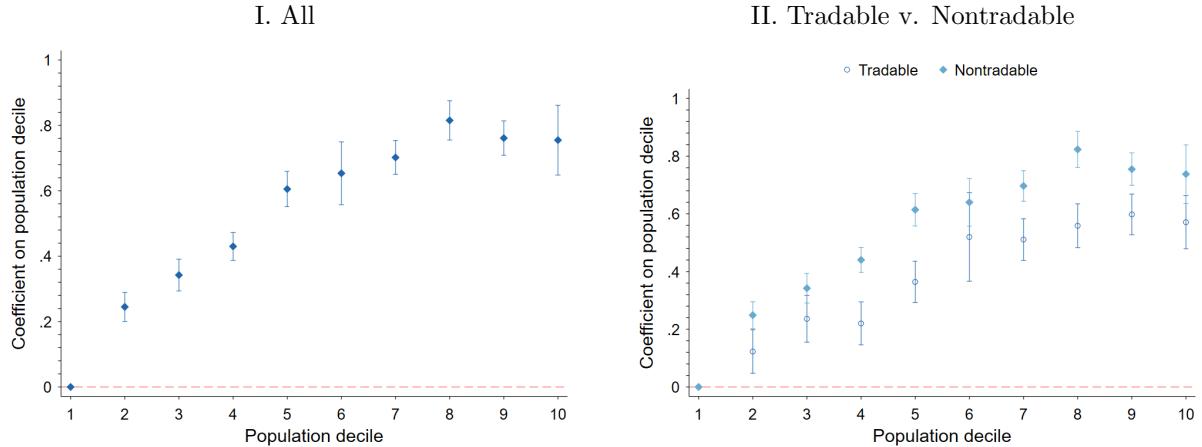

This figure presents a binned scatterplot of an indicator for the job ad's being posted by a staffing firm on log population at the CZ level.

Table A.3: Education Requirements and Staffing Firm-Posted Ads

	BA or above		HS only	
	(1)	(2)	(3)	(4)
Staffing firm	0.199*** (0.007)	0.044*** (0.002)	-0.175*** (0.006)	-0.032*** (0.002)
SOC f.e.	No	Yes	No	Yes
Number of observations	3,209,292	3,209,292	3,209,292	3,209,292
$R^2$	0.012	0.555	0.010	0.542
Mean of dep. var.	0.51	0.51	0.35	0.35

The unit of analysis is the job ad and the regression sample includes all job ads with a posted education requirement. The dependent variable is an indicator for the job requiring a college degree (column 1-2), and an indicator for the job requiring a high school degree only (column 3-4). The right-hand side includes an indicator for the job being posted by a staffing firm and, in columns 2 and 4, six-digit SOC f.e. Standard errors are clustered at the CZ level.

Figure A.2: Specialization Gradient (Including Staffing Firms)

This figure reproduces panel A of Figure 4 but includes staffing firms in the sample.

### A.3 Evaluating Online Vacancies: Representativeness and Selection

This section examines the coverage of job ads across SOC-CZ cells. It then compares the proportion of online job ads across industries to the proportion as measured in the Job Openings and Labor Turnover Survey (JOLTS).

We first characterize the coverage of job ads across SOC-CZ cells. We use the BLS 2010 version of the SOC classification, which are available in the IPUMS ACS. The IPUMS ACS has 111 four-digit SOCs that are non-aggregated and there are 722 CZs.<sup>35</sup> Of the 80,142 potential cells, about 9 percent are missing from the ACS, because rural commuting zones do not have employment in every occupation. Of the populated ACS four-digit SOC-CZ cells, the job ads data cover 71.0 percent of cells, which represent 98.3 percent of employment. The most common missing cells in the job ads data are those in the Military and those in Farm, Fishing, and Forestry occupations. Turning to two-digit SOCs, there are 722 CZs and 23 two-digit SOCs. Of the 16,606 possible cells, 0.86 percent are missing in the ACS. Our job ads data cover 90.7 percent of the remaining cells, which represent 99.8 percent of employment.

The standard resource for measuring job vacancies in the U.S. is JOLTS, conducted by the Bureau of Labor Statistics of the U.S. Department of Labor. The dataset consists of

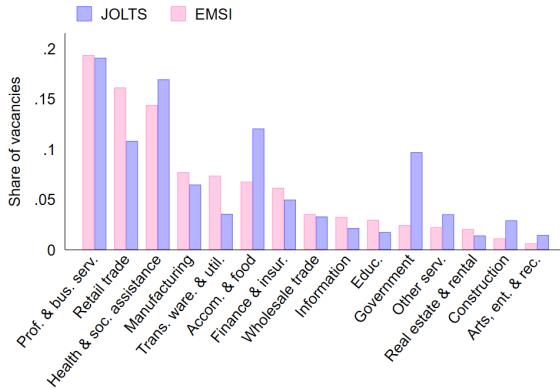

---

<sup>35</sup>Some IPUMS occupation codes are aggregated because they lack an exact match to a Census occupation code or to preserve confidentiality because there are fewer than 10,000 individuals in the cell nationwide.

monthly job openings at the national level by major industry category.<sup>36</sup> JOLTS is based on a survey of a random subset of establishments covered by state or federal unemployment insurance laws.<sup>37</sup>

Figure A.3 plots the distribution of job ads by sector for JOLTS and EMSI. Certain industries, such as Manufacturing, Finance and Insurance, and Education, have higher representation in EMSI than in JOLTS, while others, such as Health and Social Assistance, Government, and Accommodation and Food, have higher representation in JOLTS. Overall, however, there is a high correspondence in industries' vacancy shares in the two datasets.

Figure A.3: Distribution of EMSI Job Ads v. JOLTS

This figure plots the distribution of EMSI job ads and JOLTS job openings across major industries, from 2012-2017. Industries are sorted by their share of job ads in EMSI.

#### A.4 Additional Validation of Job Ads Data: Education Requirements in Job Ads v. ACS Employment, and Worker Search Behavior

In this section, again with the aim of validating the EMSI dataset, we perform two exercises. First, we compare education levels in job ads vs. ACS employed workers, across occupations and commuting zones. Second, we study the propensity of workers to search for jobs online,

<sup>36</sup>The JOLTS dataset also has vacancies at the census region level, but not at the region-by-industry level. JOLTS has no finer geographic unit than census region.

<sup>37</sup>JOLTS defines job openings as “positions that are open (not filled) on the last business day of the month. A job is ‘open’ only if it meets all three of the following conditions: (1) A specific position exists and there is work available for that position. The position can be full-time or part-time, and it can be permanent, short-term, or seasonal; (2) The job could start within 30 days, whether or not the establishment finds a suitable candidate during that time; (3) There is active recruiting for workers from outside the establishment location that has the opening.” See <https://www.bls.gov/help/def/jl.htm>. Accessed February 23, 2021.

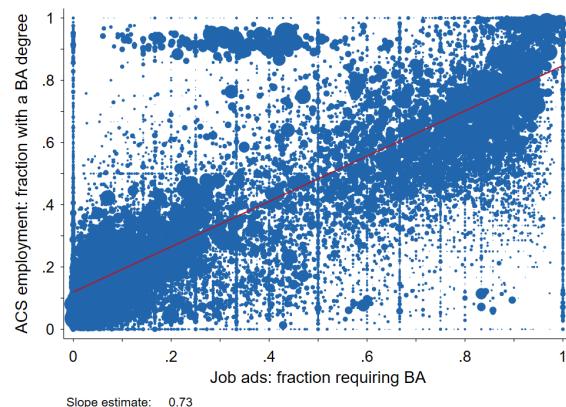

across large and small markets, for both college and non-college workers.

For each four-digit SOC  $\times$  CZ, we compute the fraction of job ads requiring a BA degree or above (in ads mentioning an educational requirement) and the fraction of employed workers, measured in the ACS, with a BA degree or higher. Figure A.4 correlates these two measures, with weights for employment in the cell. There is a strong correlation, suggesting that job ads contain valuable information about the educational requirements of the occupation. The share of ads with a given educational requirement is somewhat greater than the corresponding share of workers with that level of educational attainment. This result is perhaps unsurprising, given that job vacancies represent the frontier of occupational change, and the supply of educated workers has increased over time. Figure A.5 plots the same regression by CZ population quartile, showing a strong correlation for both large and small labor markets.

Using the same data, Figure A.6 depicts the gradient of educational requirements across CZ population deciles for the job vacancy data, and, next to it, the gradient of educational attainment of employed workers in the ACS. The gradient looks remarkably similar, both within and across occupations, suggesting again that the job vacancy data are picking up meaningful variation in the educational requirements of jobs across geography.

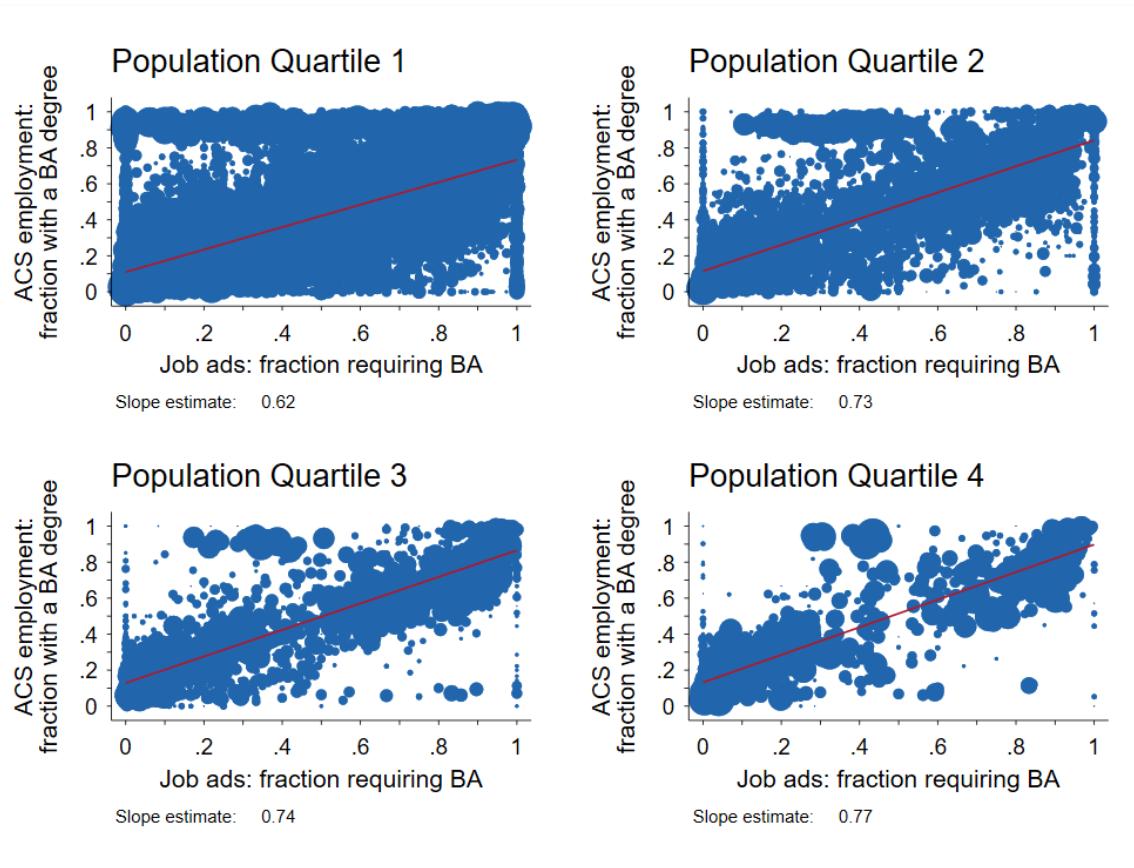

A final potential concern is that firm recruiting strategies may differ between large and small markets, due to larger pool of applicants in large markets, which may create selection into the types of jobs posted. We indirectly test this concern by studying the search behavior of workers, using the CPS Computer and Internet Use Supplement for 2011-2017. We regress an indicator for using the internet to search for jobs on CZ size decile indicators and present the results in Figure A.7. The two panels—with and without occupation fixed effects—show no evidence that using the internet for job search varies with CZ size. We perform this analysis separately for workers with a BA or above and for workers with a high school degree only. None of these analyses reveal worker search behavior differing with market size. These results provide at least suggestive evidence that selection of job postings online is not a major concern.

Figure A.4: Education of Workers in ACS v. Education Requirements in Job Ads

Each dot in the figure above corresponds to a four-digit SOC  $\times$  market. The cells are weighted by employment. The y-axis corresponds to the fraction of workers in the ACS with at least a college degree. The x-axis corresponds to the fraction of job ads that require a BA degree or higher (among ads that mention any education requirement).

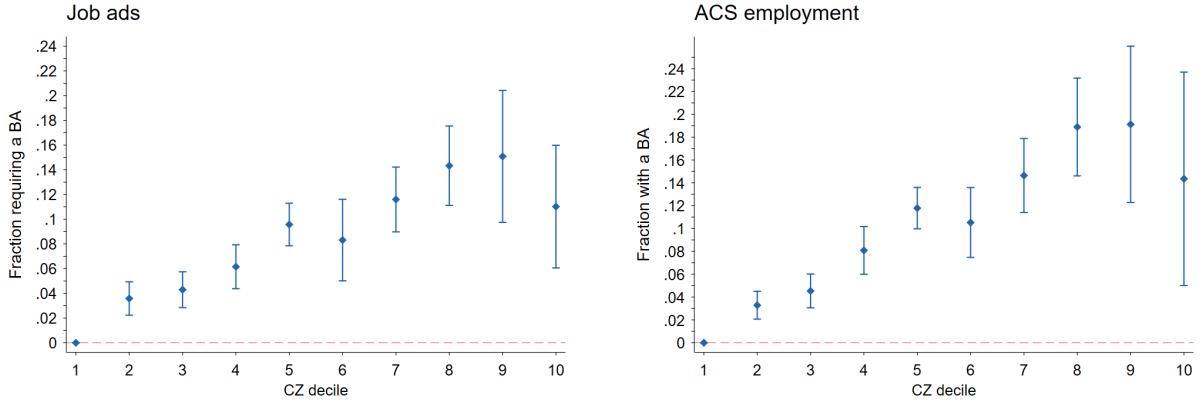

Figure A.5: Education of Workers in ACS v. Education Requirements in Job Ads

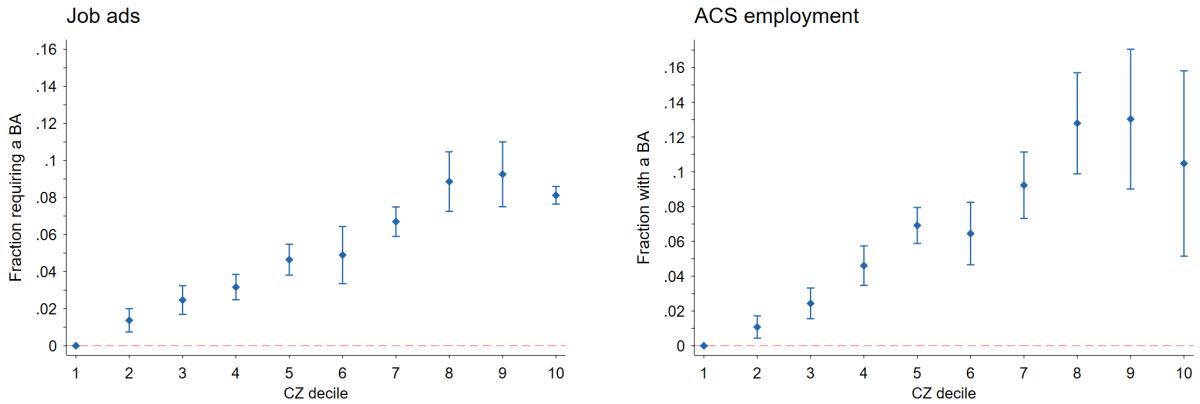

The figure above replicates Figure A.4 separately by CZ population quartile.

Figure A.6: Education Gradient with Market Size: Job Ads v. ACS Employment

### I. Without SOC f.e.

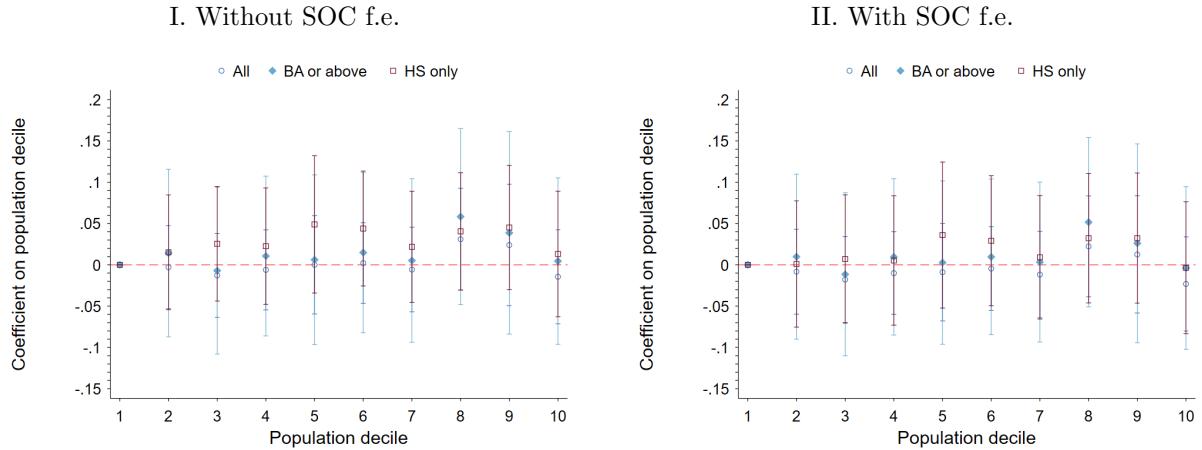

### II. With SOC f.e.

Observations are four-digit SOC-CZ pairs. The top left panel plots the coefficients in a regression of the fraction of job ads having an education requirement of a BA or above (conditional on having an educational requirement) on dummies for CZ decile. The cells are weighted by employment, and standard errors are clustered at the CZ level. The top right panel plots the same regression except where the dependent variable is the fraction of employed workers with a BA or above using the ACS. The bottom two panels reproduce the top two panels with four-digit fixed effects.

Figure A.7: Worker Job Search Using the Internet

The table above uses the CPS Computer and Internet Use Supplement for 2011-2017. The dependent variable is an indicator for the worker using the internet to search for jobs, which is regressed on a vector of deciles for CZ. Panel II includes fixed effects for CPS OCC2010 codes. Standard errors are clustered at the CZ level.

## A.5 Measuring Occupational Tasks

This section provides additional details on how we measure jobs' task content. These measures correspond to those used in past research: [Spitz-Oener \(2006\)](#) and the O\*NET database. We then compare occupations' task content—according to these measures—using the EMSI dataset with measures directly observed in the O\*NET database. These two sets of measures align, validating our use of the EMSI dataset. We also compare our data to within-occupation measures available from data collected by the Princeton Data Improvement Initiative (PDII) and find supportive evidence that our measures align with the PDII's within-occupation measures.

### Mapping Words to Tasks

We map job description words to the five [Spitz-Oener \(2006\)](#) task categories: non-routine analytic, non-routine interactive, non-routine manual, routine cognitive, and routine manual. We use the word-to-task mappings we develop in [Atalay et al. \(2020\)](#). These mappings are available on our project website: <https://occupationdata.github.io/>. We use the continuous bag of words model list of word mappings, which is described in detail in the data documentation on the website.

## Comparing Tasks from Job Ads to O\*NET

A key limitation of O\*NET is that it measures tasks only at the occupation level. Hence, O\*NET is unable to speak to geographic variation in tasks aside from those arising from different employment shares across regions. Nevertheless, O\*NET is valuable for testing the validity of our job ads for extracting occupation-level tasks. We construct occupation-level task content using the EMSI ads data and plot the correlation with O\*NET’s work activities.

The specific tasks we compare are O\*NET’s “Selling or Influencing Others,” “Communicating with Persons Outside Organization,” “Guiding, Directing, and Motivating Subordinates,” “Developing and Building Teams,” “Coaching and Developing Others,” “Coordinating the Work and Activities of Others,” and “Communicating with Supervisors, Peers, or Subordinates.” We adopt the mapping of words to O\*NET work activities listed below.<sup>38</sup> Note that this mapping is necessarily somewhat ad hoc. We count, for each ad, the total number of occurrences of any of the corresponding words. We then normalize the count so that it is expressed per 1,000 job ad words. The first two bullet points refer to interactive tasks that are external to the firm; the remaining five refer to internal interactive tasks.

- *Selling or Influencing Others:* sales marketing advertising advertise merchandising promoting telemarketing market plan
- *Communicating with Persons Outside Organization:* clients client vendor vendors public interface communicate communication communicating coordinating conferring public relation
- *Guiding, Directing, and Motivating Subordinates:* directing direction guidance leadership motivate motivating motivational subordinate supervise supervising
- *Developing and Building Teams:* team-building “team build” project leader
- *Coaching and Developing Others:* mentor mentoring coaching
- *Coordinating the Work and Activities of Others:* coordinate coordination coordinator
- *Communicating with Supervisors, Peers, or Subordinates:* peer subordinate subordinates supervisor supervisors manager managers interface communicate communication communicating coordinating conferring

---

<sup>38</sup>We count instances of each word separately; for example, “public” and “relations” are searched for separately rather than as the bigram “public relations.” We make one exception for “team build” because in our judgment “build” on its own is likely to return false positives. In Atalay et al. (2020) and in the word mappings on our project website, some task-related words are bigrams.

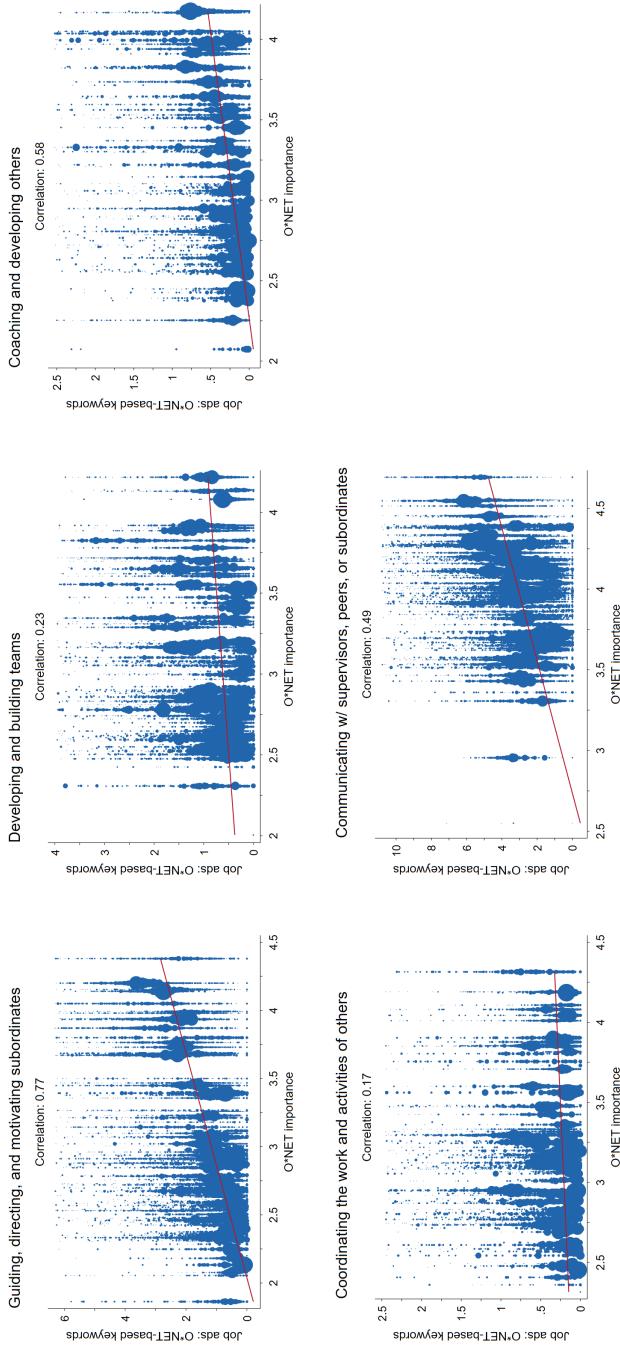

Figure A.8 demonstrates that our job ad-based task data have, for the most part, a high degree of correlation with O\*NET tasks. We should not expect a perfect correlation, as O\*NET itself has well-known limitations of small sample sizes, status quo bias, and subjective scales ([Autor, 2013](#)). But these correlations indicate that the job description text provides meaningful information about the task content of occupations.

### Comparing Occupation-Level Market Size Gradients: O\*NET v. Job Ads

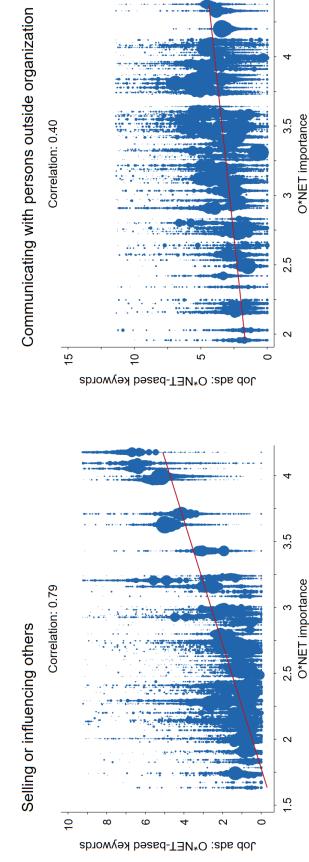

As additional evidence of the usefulness of job ads for studying job tasks in the labor market, we use occupation-level tasks extracted from job ads and compare these to widely-used occupation-level task measures from O\*NET. We ask whether we would draw similar conclusions about the task gradients with market size using job ads as we would using O\*NET, using a purely occupation-level analysis. To measure O\*NET-based tasks, we adopt the O\*NET items and categorization of [Acemoglu and Autor \(2011\)](#). We regress these tasks on CZ deciles, using ACS employment weights, and plot them in Figure A.9, panel I. We next construct our five task measures using job ads and applying the word mappings from Spitz-Oener. For this exercise, we constrain tasks to be fixed at the occupation level. We regress these tasks on CZ deciles using employment weights, and plot them in Figure A.9, panel II. The task gradients are strikingly similar across data sources, particularly for the non-routine analytic, non-routine interactive, routine cognitive and routine manual task categories, lending support to job ads data being useful for measuring tasks.

Figure A.8: Comparing Tasks from Job Ads with O\*NET

### I. Internal Interactive Tasks

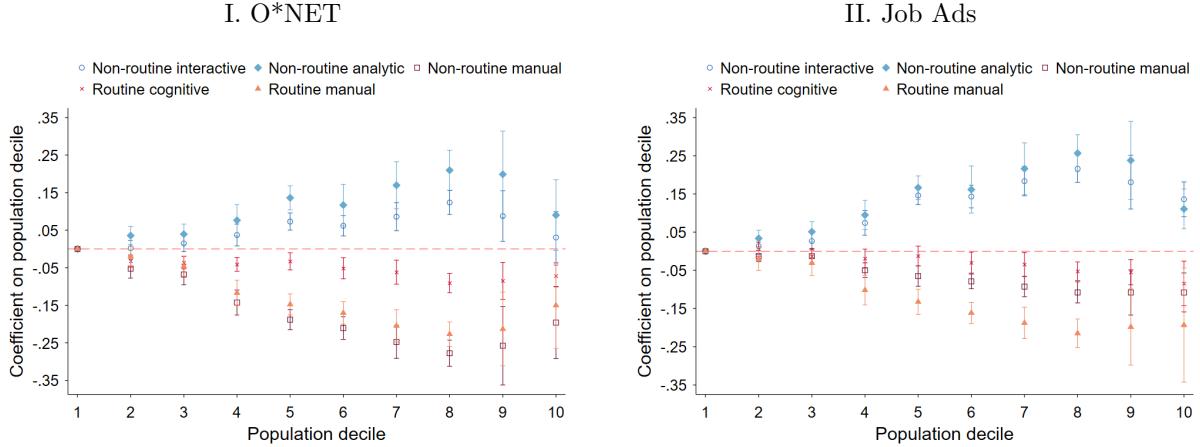

### II. External Interactive Tasks

The figures above plot the correlations between occupation-level tasks extracted from the job ads to those based on O\*NET. Each dot represents a four-digit SOC  $\times$  CZ. The correlations are weighted by ACS employment. (The figures exclude task intensities over the 99th percentile in both the reported correlations and the scatterplots.)

Figure A.9: Comparing Job Ads-based Tasks to O\*NET-based Tasks

The left panel adopts the O\*NET-based task measures and categories of Autor and Acemoglu (2011). O\*NET items are averaged at the four-digit occupation level before being standardized to have mean zero and standard deviation 1 in the labor market. The job ads-based tasks are from the Spitz-Oener task categories that are first averaged at the four-digit occupation-level and then standardized to have mean zero and standard deviation 1 in the labor market. ACS employment in four-digit occupation-CZ cells are merged to the occupation-level task measures. Each task intensity measure is regressed on CZ deciles, with ACS employment weights, and with standard errors clustered at the CZ level.

### Comparing Task Measures from EMSI to those in the Princeton Data Improvement Initiative

While useful, the preceding validation of our measurement of job task content relied solely on between-occupation task variation. In this section, we employ data from the Princeton Data Improvement Initiative (PDII)<sup>39</sup> to examine whether our measures align — looking within occupations as well — with those derived from existing datasets.<sup>40</sup>

<sup>39</sup>These data are described in [Hallock \(2013\)](#) and are used by [Autor and Handel \(2013\)](#) and [Blau and Kahn \(2013\)](#), among others.

<sup>40</sup>For our purposes, there are at least three advantages of EMSI over the PDII when measuring differences in job content between small versus large commuting zones. First, the PDII is drawn from a much smaller sample, with correspondingly large sampling error. Second, the geographic information available in the PDII include only the state of the survey respondent and whether the respondent was located in a metropolitan statistical area or not. Thus, with the PDII we cannot estimate CZ-size task gradients. Finally, the EMSI data permit measurement of individual tasks and technologies at a granular level across a wide variety of tasks and technologies, something that the PDII does not seek to measure. Nevertheless, the PDII provide the opportunity to validate our measurement of task categories using an existing, well-known dataset.

As part of the Princeton Data Improvement Initiative, 2,513 adults were asked a wide array of questions about the types of skills required and tasks performed in their jobs. From these questions, we construct indices of non-routine analytic tasks, non-routine interactive tasks, routine cognitive tasks, and manual tasks.<sup>41</sup> To compare the indices based on the PDII data to those based on EMSI job ads, we take the average values from each of the two datasets by four-digit SOC code and geography. The finest level of geography available in both datasets is the interaction of state and whether the individual resides in a metropolitan statistical area (MSA).

First, in Table A.4, we regress PDII-task measures on an indicator of whether the observation (a four-digit occupation-by-state-by-metropolitan status) is in a metropolitan area. The first four columns of this table present coefficient estimates from regressions without four-digit SOC fixed effects; the final four columns present results from specifications where these fixed effects are included. Overall, we find that individuals report spending more time on non-routine analytic tasks—and less time on routine cognitive tasks and manual tasks—in metro areas. These results align, for the most part, with those in Figure 1. There, we also report greater mentions of non-routine analytic tasks in larger CZs and fewer mentions of routine manual and non-routine manual tasks in larger CZs. The one (partial) discrepancy relates to routine cognitive tasks. In Figure 1, in specifications without fixed effects, there is a greater propensity for firms to mention routine cognitive tasks in larger CZs; this relationship disappears in specifications with SOC fixed effects. By contrast, in the PDII data, there is a lower intensity of routine cognitive tasks in metro areas.

---

<sup>41</sup>We consider (i) the frequency with which the individual takes 30 minutes to solve a problem, (ii) the frequency with which the individual uses math to solve problems, and (iii) the longest document typically read for a job as measures of non-routine analytic tasks; (i) the frequency of managing/supervising, and (ii) how much face-to-face contact with others as measures of non-routine interactive tasks; the frequency of short/repetitive tasks as our measure of routine cognitive skills; and the frequency of physical tasks as our measure of manual tasks. We could not find separate measures of routine manual and non-routine manual tasks. Before constructing each of these four indices, we standardize questions from each individual survey question. We then take the mean of these standardized values, and, finally, standardize the resulting indices.

Table A.4: Relationship Between PDII Task Measures and Metropolitan Status

	(1)	(2)	(3)	(4)	(5)	(6)	(7)	(8)
Metro	0.197*** (0.057)	-0.008 (0.061)	-0.215*** (0.047)	-0.327*** (0.057)	0.080 (0.052)	0.005 (0.058)	-0.096** (0.048)	-0.158*** (0.044)
Dependent variable	NR-Analytic	NR-Interactive	R-Cognitive	Manual	NR-Analytic	NR-Interactive	R-Interactive	R-Manual
$R^2$	0.009	0.000	0.011	0.024	0.371	0.307	0.334	0.535
Number of observations	1602	1609	1598	1607	1602	1609	1598	1607
SOC f.e.	No	No	No	No	Yes	Yes	Yes	Yes

An observation is a occupation-state-metro status triple. Observations are weighted equally. The dependent variable in each regression is the standardized index of task measures, using questions from the PDII. Standard errors are clustered at the four-digit SOC level.

In Tables A.5 and A.6, we regress measures PDII measures of task intensity against corresponding measures from our EMSI dataset. In Table A.5, occupation-by-state-by-MSA status observations are weighted equally, while in Table A.6 we weight observations according to the number of EMSI job ads in the occupation-by-state-by-MSA status triple. In unweighted specifications, we find that the PDII and EMSI data are correlated with other, but that these correlations disappear once conditioning on four-digit SOC. In weighted specifications, the two datasets' measures align not only between but also within occupations.

Overall, we conclude that patterns identified from our job ad data align reasonably well with those constructed using the PDII.

Table A.5: Relationship Between PDII and EMSI Task Measures

	(1)	(2)	(3)	(4)	(5)	(6)	(7)	(8)
Non-routine	0.837*** (0.089)				-0.006 (0.109)

SOC f.e.	No	No	No	No	Yes	Yes	Yes	Yes

An observation is a occupation-state-metro status triple. Observations are weighted according to the number of ads in the EMSI data in the occupation-state-metro status triple. The dependent variable in each regression is the standardized index of task measures, using questions from the PDII. Standard errors are clustered at the four-digit SOC level.

## A.6 Job Ad Length and Description Keywords Across Space

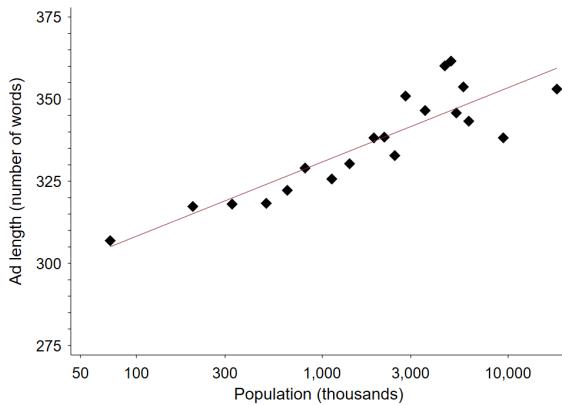

We next consider the content of the job ads and how it differs across geography. First, we plot a binned scatterplot of job ad length (i.e., the number of words) against the log CZ population (Figure A.10). This exercise shows that larger markets have longer job ads on average. Motivated by this pattern, we control for job ad length throughout our analysis and standardize our task measures to be per 1,000 ad words, and normalize our granular task measures so that each task vector has unit length.

As described in Section 2, the first step of our approach to extracting job tasks from the text to identify the part of the text corresponding to the job description. We use a set of keywords to identify this portion of the ad: “duties,” “summary,” “description,” and “tasks.” Figure A.11 examines the gradient of the job ad containing one of these keywords with market size, after controlling for ad length. The left panel shows a negligible relationship between market size and the presence of a keyword.

Lastly, we show that our novel task-extraction methodology—using job descriptions and

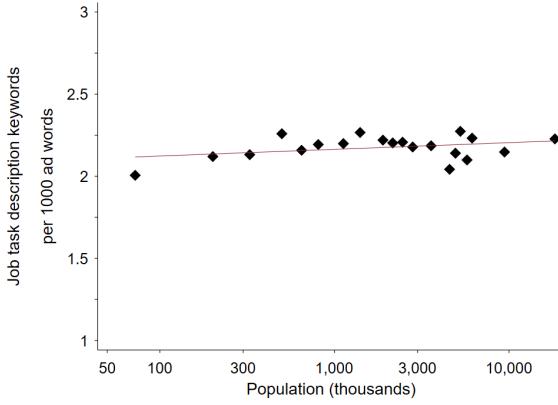

parts of speech to let the text define the job tasks—passes a simple validation check. We calculate the cosine similarity between each job and the occupation-market average, and take the average. This exercise reveals that similarity is higher for more narrowly defined occupational categories. Specifically, the cosine similarity is 0.052 for two-digit SOCs, 0.072 for four-digit SOCs, 0.104 for six-digit SOCs, and 0.166 for job titles. Thus, the text-based tasks of occupations are more similar within more narrowly defined occupational categories. It is perhaps unsurprising that narrower occupational categories share more job ad words, but this finding is reassuring and suggests that the text contains valuable information about occupational characteristics that is reflected in standard occupational classifications.

Figure A.10: Job Ad Text Across Geography

The figure above presents a binned scatterplot of job ad length (number of words) on log population at the CZ-level. Cells are weighted by the number of job ads in the cell.

Figure A.11: Job Description Keywords Across Geography

The figure above presents a binned scatterplot of an indicator of the job ad's having a keyword in our task-extraction algorithm—"responsibilities," "duties," "summary," "tasks"—normalized per 1,000 ad words, against log CZ population.

## B Task Extraction and Validation

This section outlines our approach to measuring job tasks. We illustrate the algorithm and present the most common tasks, the list of excluded tasks, and a scatterplot of the number of granular tasks and market size (Appendix B.1); present a validation exercise using multi-establishment firms (B.2); present the most common technologies (Appendix B.3); evaluate the relationships among tasks, technologies, and market size (Appendices B.4 and B.5); and show that these tasks account for variation in wages across geography, above and beyond what is captured by occupational codes (Appendix B.6).

### B.1 Task List

We first present two sample ads and the granular tasks extracted by the algorithm in Table B.1.

Table B.1: Illustrating the Algorithm to Extract Verb-Noun Tasks

Job Title	Job Ad Text	Tasks Extracted
Electrician	<p>licensed electrician electronic control systems is seeking a full_time licensed electrician to <b>perform</b> commercial , residential , and industrial electrical <b>maintenance</b> and repair . candidates would be <b>assisting clients</b> in dade , bro ward and palm beach counties . candidate must be organized and motivated as we are looking for a person with skills and good working habits . specific responsibilities include , but are not limited to : assembling , installing , testing and maintaining electrical or electronic wiring , equipment , appliances , apparatus and fixtures <b>using hand</b> tools and power tools . diagnosing malfunctioning systems and components connecting wires to circuit breakers , transformers or other components . inspecting electrical systems , equipment and components to identify hazards , defects and the need for adjustment or repair , and to <b>ensure compliance</b> with codes . maintaining current electrician 's license or identification card to meet governmental regulations . licensed electrician active journeyman electrician must be licensed 5 years of experience minimum ( residential , commercial &amp; industrial ) proficient knowledge of local codes and safety regulations must speak fluent english work in dade , bro ward and palm beach counties must_have valid drivers_license and dependable transportation</p>	<p>perform maintenance, assisting clients, use hands, ensure compliance</p>
Assistant Store Manager	<p>general_summary : as a family dollar assistant store manager you will responsible for <b>providing</b> exceptional <b>service</b> to our customers . a key priority includes assisting the store manager in the daily operation of the store . under the direction of the store manager , you will also be responsible for <b>maintaining inventories</b> , <b>store</b> appearance and completing daily paperwork . principal duties &amp; responsibilities : greets and <b>assists customers</b> in a positive , approachable manner . answers questions and resolves customer inquiries and concerns . maintains a presence in the store by <b>providing</b> excellent <b>customer service</b> . <b>ensures</b> a clean , well_stocked <b>store</b> for customers . at the direction of the store manager , supervises , trains , and develops store team members on family dollar operating practices and procedures . assists in unloading all merchandise from delivery truck , organizes merchandise , and transfers merchandise from stockroom to store . <b>assists store</b> manager in ordering merchandise and record_keeping to include payroll , scheduling and cash_register deposits and receipts . supports store manager in loss_prevention efforts . assumes certain management responsibilities in absence of store manager . <b>follows</b> all <b>company</b> policies and procedures . back f6f5fe bets arc setter maintaining store store .</p>	<p>provide service, maintaining inventory, maintain store, assisting customers, provide customer_service, ensure stores, assist store, following company</p>

The table above presents the full text of two sample job ads and highlights in bold the verb-noun tasks extracted by our algorithm. Note that not all verb-noun pairs in the job ad text are highlighted as tasks because we define the set of tasks as the 500 most common verb-noun pairs.

Next, we list the 399 tasks we extract from the job ad text as verb-noun pairs along

with the fraction of ads with each task ( $\times 100$ ). For readability, instead of listing the word stems we present the verb-noun pairs as they appear in their first occurrence, which leads to variations in noun forms and verb conjugations in the table (e.g., “provide service” vs. “providing support”).

Table B.2: Tasks Extracted from Verb-Noun Pairs

As described in the text, we exclude 101 tasks from the original list of 500 most common verb-noun pairs, using our judgment to select pairs that do not correspond to tasks. These excluded verb-noun pairs are presented below and describe worker skills (e.g., “high

school diploma,” “ged years,” “required bachelor”); firm attributes (e.g., “is company,” “is equal\_opportunity”); aspects of the job search process (“pass drug”); or are simply uninformative (“meet needs,” “be duties”).

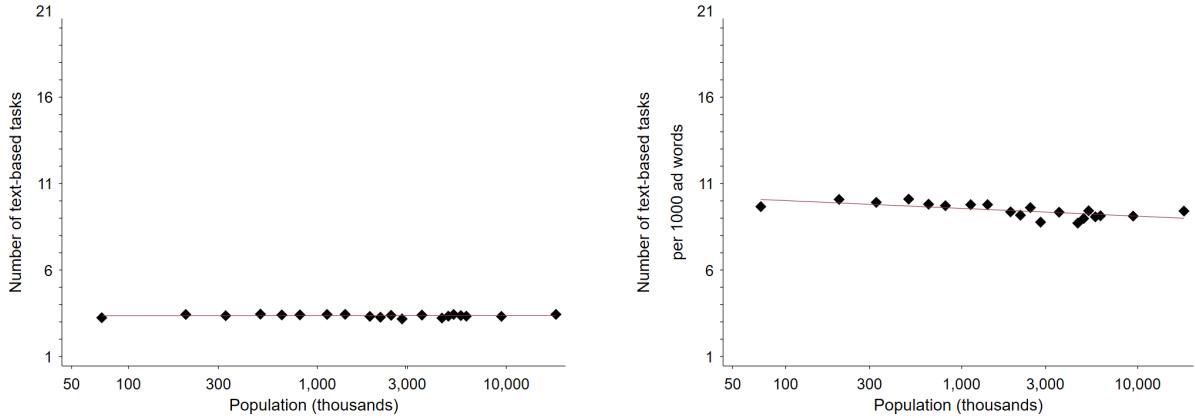

Table B.2 (continued): Verb-Noun Pair Drop List

be years	be doors	is job
is equal_opportunity	can doors	be company
arc bach	are business	perform duties
must years	requested react	be part
high_school diploma	are store	work environment
demonstrated ability	including evenings	perform functions
required employee	is law	required knowledge
bachelor degree	is customer	have experience
meet needs	earned degree	are position
required ability	is ability	have years
required years	send resume	required qualifications
required skills	s journal	is service
according state	eas program	includes ability
include customers	is delivery	committed diverse
work hours	are company	are sales
are customers	ged years	knowledge skills
be customer	include duties	working business
preferred years	required position	desired skills
required experience	be duties	providing product
s degree	pass drug	be lbs
arc setter	required bachelor	are manages
end caps	are accordance	are duties
preferred experience	sporting goods	is walks
including products	have ability	will career
is position	based business	are reporting
work part	ensuring aspects	according needs
are time	assigned job	permitted law
ensure execution	be ability	performing tasks
bach bets	may duties	playing role
be team	are fast_growing	preferred knowledge
travel travel	requires state	achieve results
is experience	must_have driver	completing tasks
may materials	will business	performing work
are drafts	s level	

Figure B.1 presents the frequency of text-extracted job tasks per ad. The left panel is a

binscatter of number of tasks at the ad level on CZ size, while the right panel presents the same figure but first normalizes the number of tasks per 1,000 ad words. There are about four tasks per ad on average (out of 399 total tasks), and when we normalize by ad length, as in the right panel, the number of tasks decreases with market size.

Figure B.1: Number of Tasks and Market Size

The left panel above presents a binned scatterplot of number of tasks against log CZ population. The right panel presents the same figure, except the dependent variable is normalized per 1,000 ad words.

## B.2 Comparing Tasks in a Firm’s Headquarters v. Other Establishments

In this section, we compare the intensity of tasks in a firm’s headquarters relative to its other establishments. We find that systematic differences align with our priors about the tasks that take place in headquarters. As a result, we conclude that the EMSI data and our extraction of granular tasks provide a useful new characterization of differences in work activities between geographies.

For this exercise, we limit ourselves to the 10 largest firms, measured by total job postings, and exclude chains and postings by government agencies. We identify the headquarters location for each firm as the CZ with the largest number of the firm’s postings and then validate this list against public records. The list of firms used for this validation exercise, along with their headquarters location, are: Amazon (Seattle, WA), Genesis HealthCare (Kennett Square, PA), UnitedHealth Group (Minnetonka, MI), IBM (Armonk, NY), HCA Health-care (Nashville, TN), Lockheed Martin Corporation (Bethesda, MD), Aramark Corporation

(Philadelphia, PA), Providence Health and Services (Renton, WA), Citigroup Incorporated (New York, NY), Parallon (Nashville, TN). This subsample includes 136,324 ads. We run a regression at the job-ad level for each task. We regress task intensity on an indicator for the job being in the firm headquarters, along with six-digit SOC fixed effects, and with the standard errors clustered at the CZ-level. In Table B.3, we report the tasks with the largest positive and negative coefficient estimates on headquarters (after standardizing, by dividing by the task standard deviation). The list of largest positive and negative gradients are presented. A clear pattern emerges, which is that the headquarters locations require management, teamwork, or span of control: managing projects, communication (both written and oral), analyzing data, and identifying opportunities are all tasks that reflect these types of work activities. The tasks with the largest negative gaps—i.e., tasks that are common in non-headquarters locations relative to the headquarters—involve training and working with or assisting clients. Overall, we view these intuitive differences as an additional validation of our approach.

Table B.3: Tasks with Largest Gap Between Headquarters and Non-Headquarters Locations

Positive gradient		Negative gradient	
Task	$\hat{\beta}_{hq}$	Task	$\hat{\beta}_{hq}$
written communication	0.2714	on_going training	-0.3949
managing projects	0.2041	provides training	-0.3694
growing business	0.1910	work projects	-0.3409
written oral_communication	0.1717	requires travel	-0.2930
detail ability	0.1603	existing clients	-0.1394
will teams	0.1359	include client	-0.1310
analyzing data	0.1292	work others	-0.1098
support business	0.1243	assisting clients	-0.1039
working team	0.1235	meet clients	-0.1011
sells products	0.1106	provide assistance	-0.0897
identify opportunities	0.0923	stand walk	-0.0800
provides quality	0.0910	written skills	-0.0785
meet deadlines	0.0857	assume responsibilities	-0.0772
serving customers	0.0851	providing solutions	-0.0593
seek customer	0.0847	increase sales	-0.0591

The table above is based on a subsample of 136,324 ads from the following multi-establishment firms: Amazon, Genesis HealthCare, UnitedHealth Group, IBM, HCA Healthcare, Lockheed Martin Corporation, Aramark Corporation, Providence Health and Services, Citigroup Incorporated, and Parallon. We run a regression at the job-ad level for each of the 399 tasks. We regress the task intensity on an indicator for the job being in the firm headquarters, along with six-digit SOC fixed effects, and with the standard errors clustered at the CZ-level. We report the tasks with the largest positive and negative coefficient estimates on headquarters (after standardizing, by dividing by the task standard deviation). The list of the 15 largest positive and negative gradients are presented. All estimates are significant at the 5 percent level.

### B.3 Technology List

The table below lists the O\*NET Hot Technologies that we identify in the job ads text along with the fraction of ads with each technology ( $\times 100$ ). To be counted as a technology appearance, all words in the technology name must appear in the vacancy text, although we do not require that the words appear in order.

For the three social media technologies in the list (Facebook, YouTube, and LinkedIn), we explicitly search for and exclude false positives in our analysis. To identify false positives, we search for phrases that strongly suggest the ad is directing the reader to visit or follow the firm on social media. For example, any of the following bracketed phrases along with the mention of “facebook” would be flagged as a false positive for the Facebook technology: “[fan us][visit us][like us][connect with us][follow us][check us out][for more information][please

visit][share this job][how did you hear][look for us][learn more about] ... facebook.” We perform the analogous exercise to create false positive flags for YouTube and LinkedIn. We conducted robustness to our method of identifying false positives, such as creating a “true positive” flag that explicitly identifies the phrase “social media” along with other words, such as “knowledge,” “experience,” or “proficiency” in the ad, and the results are unchanged.

Table B.4: Technologies Extracted from Job Vacancy Data (with Frequency per 100)

## B.4 Tasks and Market Size

Tables B.5 and B.6 reproduce Tables 2 and 3, respectively, except with a continuous measure of market size on the right-hand side—log population—rather than market size decile indicators. The tasks with the largest positive and negative gradients are similar to those presented in Section 3. Table B.7 re-estimates equation (1) using a predetermined list of verbs from Michaels et al. (2018) instead of our task list extracted from the text itself. The takeaway is quite similar. Using only the Michaels et al. (2018) verb list, more abstract or non-routine verbs, such as “design,” “project,” “research,” and “manage,” have the steepest

positive gradient, while more routine verbs, such as “store,” “clean,” and “count,” and manual verbs, such as “fuel” and “rotate,” have the steepest negative gradient.

Table B.5: Tasks with the Steepest Gradient in Log Population

Positive Gradient				Negative Gradient			
No SOC f.e.		SOC f.e.		No SOC f.e.		SOC f.e.	
Task-Population	$\hat{\beta}$	Task	$\hat{\beta}$	Task-Population	$\hat{\beta}$	Task	$\hat{\beta}$
written communication	0.0451	written skills	0.0134	maintain store	-0.0414	maximizes profitability	-0.0303
managing projects	0.0367	achieving sales	0.0121	operating cash_register	-0.0393	protect company	-0.0288
providing support	0.0294	ensure safety	0.0115	provide customer_service	-0.0380	maintain store	-0.0272
develop solutions	0.0269	stand walk	0.0113	protect company	-0.0357	operating cash_register	-0.0256
problem_solving skills	0.0268	prioritize tasks	0.0111	maximizes profitability	-0.0350	make changes	-0.0236

work projects	0.0234	driving sales	0.0105	assist store	-0.0313	procedures cash	-0.0215
support business	0.0230	supervising store	0.0104	make changes	-0.0298	skating carhop	-0.0198
written skills	0.0219	providing environment	0.0102	maintaining inventory	-0.0274	unloading trucks	-0.0186
developing strategies	0.0217	meet deadlines	0.0101	procedures cash	-0.0273	ensure employees	-0.0185
provide guidance	0.0212	written communication	0.0100	following company	-0.0264	drive_in employees	-0.0177
identify opportunities	0.0207	identify opportunities	0.0099	preventing trafficking	-0.0264	assigned store	-0.0176
develop business	0.0205	exceed sales	0.0097	unloading trucks	-0.0257	maintaining inventory	-0.0175
will teams	0.0200	provide feedback	0.0097	skating carhop	-0.0255	provide customer_service	-0.0173
working team	0.0198	managing projects	0.0096	assigned store	-0.0251	working store	-0.0161

The table above reproduces Table 2 except replaces the right-hand side market size decile indicators with a continuous log population measure. The coefficients above present the tasks with the steepest positive and negative gradients with respect to market size, as captured by  $\hat{\beta}$  on the continuous population measure. All coefficients are statistically significant at the 1 percent level, except “supervising store” in column 3 ( $p = 0.091$ ).

Table B.6: Technologies with the Steepest Gradient in Log Population

All		College		High School	
Technology	$\hat{\beta}$	Technology	$\hat{\beta}$	Technology	$\hat{\beta}$
Linux	0.0361	Python	0.0352	Microsoft Excel	0.0174
JavaScript	0.0324	Linux	0.0327	Microsoft Outlook	0.0127
Python	0.0319	JavaScript	0.0317	Microsoft Office	0.0108
Unix	0.0309	Unix	0.0283	Microsoft Word	0.0102
Microsoft Excel	0.0288	Ruby	0.0249	Chef	0.0097
Microsoft Project	0.0272	C++	0.0246	Microsoft Powerpoint	0.0088
C++	0.0256	SAS	0.0222	Microsoft Access	0.0086
Oracle Java	0.0220	Microsoft Project	0.0219	Linux	0.0068
SAP	0.0215	Oracle Java	0.0215	Epic Systems	0.0065
Microsoft Access	0.0209	Microsoft Excel	0.0203	Swift	0.0061
SAS	0.0205	Git	0.0198	Citrix	0.0060
MySQL	0.0202	Ajax	0.0198	Tax Software	0.0056
Git	0.0199	MySQL	0.0196	Facebook	0.0056
Microsoft Office	0.0196	Tableau	0.0195	Microsoft Sharepoint	0.0056
Microsoft Powerpoint	0.0193	NoSQL	0.0187	Python	0.0054

We reproduce Table 3 by re-estimating equation 1 except replacing the right-hand side market size decile indicators with a continuous log population measure. All estimates are statistically significant at the 1 percent level, with the following exceptions: C++ in the college column ( $p = 0.025$ ) and Swift in the high school column ( $p = 0.017$ ).

Table B.7: Verbs with the Steepest Gradient

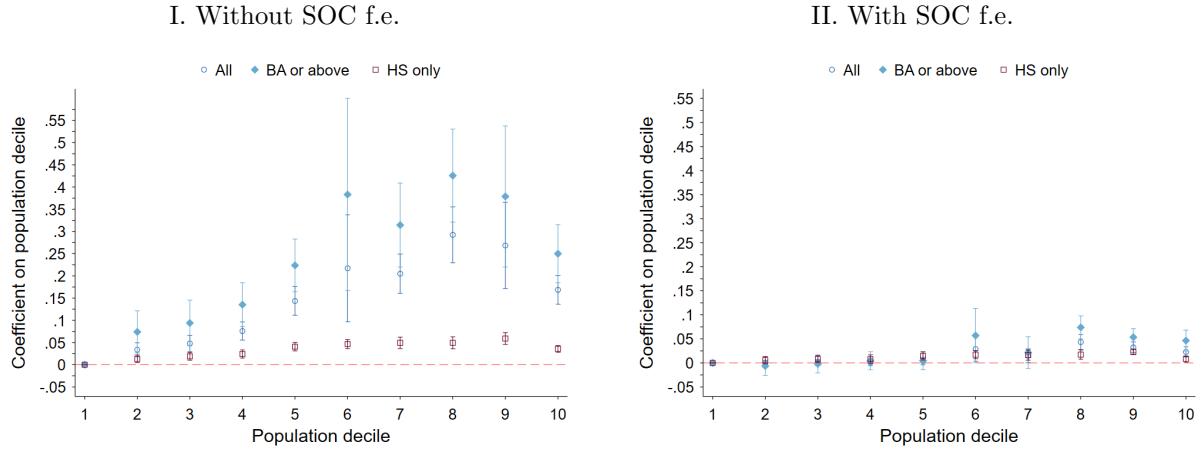

Positive gradient		Negative gradient	
Task	$\hat{\beta}_{10}$	Task	$\hat{\beta}_{10}$
design	0.0812	pay	-0.0625
project	0.0797	truck	-0.0623
experience	0.0660	store	-0.0559
research	0.0632	earn	-0.0513
develop	0.0616	clean	-0.0506
manage	0.0581	license	-0.0452
web	0.0560	fuel	-0.0448
finance	0.0499	get	-0.0421
analyze	0.0492	rotate	-0.0396
process	0.0483	authorize	-0.0392
create	0.0461	count	-0.0362
content	0.0437	trash	-0.0321
lead	0.0432	average	-0.0320
market	0.0431	retail	-0.0307
track	0.0426	sign	-0.0301

The table above reproduces Table 2, except it uses the list of verbs from Michaels et al. (2018). This exercise is conducted on a 1 percent sample of all job ads, rather than 5 percent, for computational speed, since the verb list includes 1,665 verbs. All estimates are statistically significant at the 1 percent level.

## B.5 Technology Requirements and Market Size

We check the sensitivity of our result on the market size gradient of technologies with respect to our decision to exclude R and C from the technology list. Figure B.2 reproduces Figure 3 but includes the technologies R and C, which are potentially susceptible to false positives in processing the job vacancy text. Our main result is largely unaffected.

Figure B.2: The Technology Gradient (including R and C)

The figure above reproduces Figure 3 but includes the technologies R and C.

## B.6 Wages and Tasks Across Space

This section demonstrates that tasks extracted from job vacancy ads account for variation in wages across geography, above and beyond what is captured by occupational codes.

For this analysis, we construct occupation-education-market average tasks from the job ads data. We then merge mean wages at the occupation-education-market level from the IPUMS-ACS. We then regress log wages on tasks, with different sets of controls. All regressions are weighted by employment in the cell.

Note that these regressions probably underestimate the explanatory power of job tasks in accounting for wage variation, since we do not observe ad-level wages and these are regressions of mean wages on mean tasks, using variation across geography-education cells. While it is tempting to interpret these estimates as hedonic regressions that are delivering “task prices,” we should avoid this interpretation because tasks are endogenous to unobserved worker sorting or job characteristics.

Table B.8 first shows that task variation across geography accounts for variation in wages above and beyond what is captured by occupation fixed effects. This result can be seen by the statistically significant coefficients on tasks in columns 3-6. Note that the slight increase in  $R^2$  between columns 2 and 3 indicates that the five task categories capture only 0.1 percent of wage variation beyond occupation categories. Column 4 adds to the regression the granular task measures averaged to the occupation-education-market cell. The granular task measures account for an additional 1.9 percent of wage variation, as seen by comparing  $R^2$  between columns 3 and 4. Thus, the granular tasks extracted from job descriptions

capture meaningful information about job tasks that are reflected in wages. Note that for jobs requiring a college degree, non-routine analytic tasks have a stronger relationship with wages than for jobs requiring a high school diploma only.

Table B.9 presents regressions of log wages on log population, tasks, and tasks interacted with population. In the coefficient on log-population, we confirm the finding in the literature that the relationship between population and wages is stronger for higher educated workers. We also see that the interaction terms between population and tasks appears important. For example, column 2 shows that an increase in interactive tasks in larger labor markets accounts for higher wages of jobs requiring a college degree, while an increase in interactive tasks for jobs requiring a high school diploma has a weaker correlation with wages. Note that this table uses *within-occupation* variation in tasks across geography in accounting for higher wages. Overall, Tables B.8 and B.9 show that task variation across space accounts for variation in wages above and beyond occupation codes.

Table B.8: Wages and Tasks

	Baseline				HS only	BA or above
	(1)	(2)	(3)	(4)	(5)	(6)
Non-routine analytic	0.229*** (0.013)		0.050*** (0.010)	0.043*** (0.012)	0.020** (0.008)	0.060*** (0.016)
Non-routine interactive	0.085*** (0.012)		-0.003 (0.006)	-0.009 (0.006)	0.013 (0.010)	-0.005 (0.009)
Routine cognitive	-0.008** (0.004)		-0.021*** (0.004)	-0.003 (0.004)	-0.025*** (0.005)	-0.014 (0.011)
Routine manual	0.059*** (0.005)		-0.018*** (0.006)	-0.009* (0.005)	-0.020*** (0.006)	-0.056*** (0.011)
Non-routine manual	0.040*** (0.008)		0.010* (0.005)	0.001 (0.005)	0.005 (0.005)	-0.057*** (0.013)
SOC f.e.	No	Yes	Yes	Yes	Yes	Yes
Text-based tasks	No	No	No	Yes	No	No
Number of observations	58,494	58,494	58,494	58,494	33,859	24,635
$R^2$	0.489	0.784	0.785	0.803	0.552	0.694
Adjusted $R^2$		0.784	0.785	0.802	0.551	0.693
Mean of dep. var.	10.65	10.65	10.65	10.65	10.44	10.94

The unit of observation is the occupation-education-market. The dependent variable is log wages, regressed on Spitz-Oener (2006) task-related keywords per 1,000 ad words, which are standardized to have mean zero and standard deviation one across ads before averaging to the cell. Column 4 includes the verb-noun tasks averaged to the occupation-education-market cell. Education category dummies are included in columns 1-4. Regressions are weighted by employment. Standard errors are clustered at the CZ level.

Table B.9: Wages and Task-Population Gradient

	HS only (1)	BA or above (2)
Log pop.	0.043*** (0.006)	0.013*** (0.004)
× non-routine analytic		
Log pop.	0.015** (0.006)	0.029*** (0.006)
× non-routine interactive		
Log pop.	0.002 (0.002)	0.009 (0.007)
× routine cognitive		
Log pop.	-0.018*** (0.003)	-0.012*** (0.004)
× routine manual		
Log pop.	0.002 (0.003)	-0.014 (0.009)
× non-routine manual		
Log population	0.076*** (0.007)	0.081*** (0.008)
SOC f.e.	Yes	Yes
Number of observations	33,859	24,635
$R^2$	0.594	0.766
Mean of dep. var.	10.44	10.94

The unit of observation is the occupation-education-market. The dependent variable is log wages, which is regressed on four-digit SOC f.e., tasks, log population, and log population interacted with tasks. Tasks are standardized to have mean zero and standard deviation one across ads before averaging to the cell. Regressions are weighted by employment. Task coefficients are not reported above. Standard errors are clustered at the market level. Tasks correspond to the classification in [Spitz-Oener \(2006\)](#).

## C Analysis Appendix

This section presents tables and figures to supplement the main analysis.

### C.1 Appendix to Sections 3.1 and 3.2

In this appendix, we present additional tables and figures on the relationships among job tasks and population.

#### Within-Between Decompositions

To further evaluate how much of the variation in occupational tasks across geography is due to within- versus between-occupation variation in task content, we perform a simple decomposition. Denote the average task  $k$  content in market size quartile  $q$  as,  $t_{kq} = \sum_{o \in \mathcal{O}} t_{koq} s_{oq}$ ,

where the average task content of each occupation  $o$  in quartile  $q$ ,  $t_{koq}$ , is multiplied by occupation  $o$ 's share of quartile  $q$ 's employment,  $s_{oq}$ . We express the difference in task content between two quartiles,  $q$  and  $\tilde{q}$ , as

$$t_{kq} - t_{k\tilde{q}} = \sum_{o \in \mathcal{O}} (t_{koq} - t_{ko\tilde{q}}) \bar{s}_{oq\tilde{q}} + \sum_{o \in \mathcal{O}} \bar{t}_{koq\tilde{q}} (s_{oq} - s_{o\tilde{q}}), \quad (5)$$

where  $\bar{s}_{oq\tilde{q}} = (s_{oq} + s_{o\tilde{q}})/2$  and  $\bar{t}_{koq\tilde{q}} = (t_{koq} + t_{ko\tilde{q}})/2$ . The first term on the right-hand side of equation (5) represents the within component, and the second term represents the between component. Dividing both sides by  $(t_{kq} - t_{k\tilde{q}})$  yields the within and between shares.

Table C.1 presents the results of this decomposition. For non-routine analytic tasks, 14 percent of the variation between 1st quartile and 4th quartile CZs is within occupation. For non-routine interactive tasks, the corresponding figure is 22 percent. This result implies that standard data sources fail to capture much of the variation in tasks between small and large labor markets.

We perform the decomposition on each of our granular task measures to understand how much of the variation in these tasks across markets occurs within occupations versus between occupations. We calculate the decomposition shares for each of the granular tasks and report the median. We find that 18 percent of the variation from smallest to largest quartile CZs occurs within occupations. Applying the equation (5) decomposition to the number of technologies, we find that about 79 percent of the variation in technologies between 1st quartile CZs and 4th quartile CZs occurs between occupations and about 21 percent within occupations.

Table C.2 examines the sensitivity of our within-between decomposition of Table C.1 to measurement error. To do so, we randomly assign ads to population quartiles, in proportion to the actual distribution of six-digit SOCs across quartiles. We then reproduce the within-between decomposition exercise of Table C.1. Since we randomize ads to quartiles, the within shares should be close to zero or exactly zero. Table C.2 shows that most of the within shares are close to zero and most of the between shares are close to one, as we would expect if measurement error were not a major concern. This pattern notably holds for the Q4-Q1 decompositions. There are a couple of exceptions to this pattern, such as the routine cognitive decompositions for the Q4-Q3 and Q3-Q2 differences. However, in those cases the within shares are less meaningful, as the differences in average tasks (the denominators in the decompositions) are near-zero. Overall, the main takeaway from Table C.2 is that our within-between decompositions are robust to measurement error.

## Evidence for Jobs Being Jointly Intensive in Interactive and Analytic Tasks

We consider whether jobs that are jointly intensive in interactive and analytic tasks appear predominantly in large markets. We place each job into one of four groups, based on whether it is above or below the median non-routine interactive task content, and above or below the median non-routine analytic task content. We then plot, for each CZ population decile, the difference between the proportion of jobs in each of the four groups relative to the proportion of jobs in the same group in the first CZ decile. This plot is presented as the left panel of Figure C.1. We find that jobs that are intensive in *both* analytic and interactive tasks make up 12.3 percentage points more of jobs in the highest decile compared with the lowest decile. Jobs that are intensive in only analytic tasks but not interactive tasks make up only about 3.4 percentage points more of jobs in the highest decile, while jobs that are only interactive but not analytical make up a smaller share of total jobs in the highest decile markets, relative to smallest decile markets. This finding holds even after removing the mean task content at the six-digit SOC level before categorizing into the four groups, as seen in the right panel of Figure C.1.

## Internal and External Interactive Tasks by Education

In Figure C.2, we explore whether the gradients presented in Figure 2 differ according to the jobs' educational requirements. For the most part, gradients are steeper for jobs requiring a college degree. However, in specifications with six-digit SOC fixed effects, the difference between these gradients is minor.

## Sensitivity to Time Period

In Figure C.3, we explore whether the key tasks and technologies gradients of Figures 1 and 3 might be sensitive to the time period studied. Specifically, a potential concern is that a rapidly changing labor market in large v. small CZs might generate changing gradients over time. To explore this issue, we divide the sample period into two approximately equal periods, 2012-2014 and 2015-2017, and re-estimate panel I of each of the two figures. The results are highly stable across the two time periods.

## Market Density and Tasks and Technologies

We next assess whether the task and technology patterns with respect to CZ population size, observed in Figures 1-4, also hold with respect to CZ population density. We construct CZ population density deciles. Then, we reproduce Figures 1-4 using population density deciles,

as opposed to population size deciles, as the explanatory variables of interest. The coefficient estimates are presented in Figures C.4-C.7.

Table C.1: Task Decomposition Across Markets

	NR-Analytic	NR-Interactive	NR-Manual	R-Cognitive	R-Manual	Granular Tasks	Technologies
Q1	5.30	5.66	0.81	0.71	2.74		0.12
Between and Within Occupational Decomposition							
Between	Within	Between	Within	Between	Within	Between	Within
Q2-Q1	0.80	0.20	0.79	0.21	1.35	-0.35	0.50
Q3-Q2	0.92	0.08	0.83	0.17	0.53	0.47	-4.12
Q4-Q3	1.01	-0.01	0.70	0.30	0.72	0.28	0.07
Q4-Q1	0.86	0.14	0.78	0.22	0.51	0.49	1.68

81	Q2-Q1	0.80	0.20	0.79	0.21	1.35	-0.35	1.06	-0.06	0.50	0.50	0.57	0.43	0.84	0.16	
	Q3-Q2	0.92	0.08	0.83	0.17	0.53	0.47	0.47	-4.12	5.12	0.59	0.41	0.61	0.39	0.79	0.21
	Q4-Q3	1.01	-0.01	0.70	0.30	0.72	0.28	0.07	0.93	0.72	0.28	0.28	0.04	0.96	0.36	0.64
	Q4-Q1	0.86	0.14	0.78	0.22	0.51	0.49	1.68	-0.68	0.57	0.43	0.82	0.18	0.79	0.21	

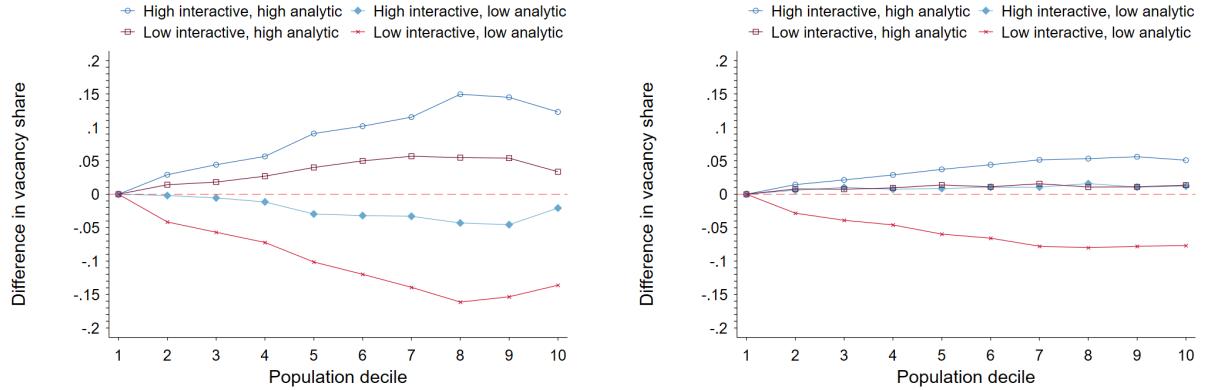

This table presents the results of the decomposition of equation (5) for each of the five task categories (non-routine analytic, non-routine interactive, non-routine manual, routine cognitive, and routine manual), each granular task (reporting the median), and the number of technologies. The top panel reports the average task content and the average number of technologies in each of four market size quartiles. Tasks in the top panel are expressed as number of task-word mentions per 1,000 ad words, and technologies are expressed as the average number of technologies mentioned per ad. The bottom panel presents the within and between shares of the total difference between population quartiles. The decomposition for granular tasks is constructed by first calculating the decomposition for each of the 399 tasks separately and then taking the median of the within and between shares.

Table C.2: Task Decomposition Across Markets: Sensitivity to Measurement Error

	NR-Analytic	NR-Interactive	NR-Manual	R-Cognitive	R-Manual	Granular Tasks	Technologies
Q1	5.51	5.78	0.80	0.69	2.58		0.14
Q2	6.41	6.14	0.81	0.77	2.45		0.21
Q3	7.41	6.46	0.78	0.79	2.27		0.31
Q4	7.70	6.71	0.75	0.79	2.19		0.32
	Between and Within Occupational Decomposition						
	Between	Within	Between	Within	Between	Within	Between
Q2-Q1	1.00	0.00	0.99	0.01	0.93	0.07	1.01
Q3-Q2	1.01	-0.01	1.03	-0.03	0.94	0.06	0.85
Q4-Q3	0.96	0.04	0.98	0.02	1.02	-0.02	0.13
Q4-Q1	1.00	0.00	1.00	-0.00	0.98	0.02	0.99
	Within	Between	Within	Between	Within	Between	Within

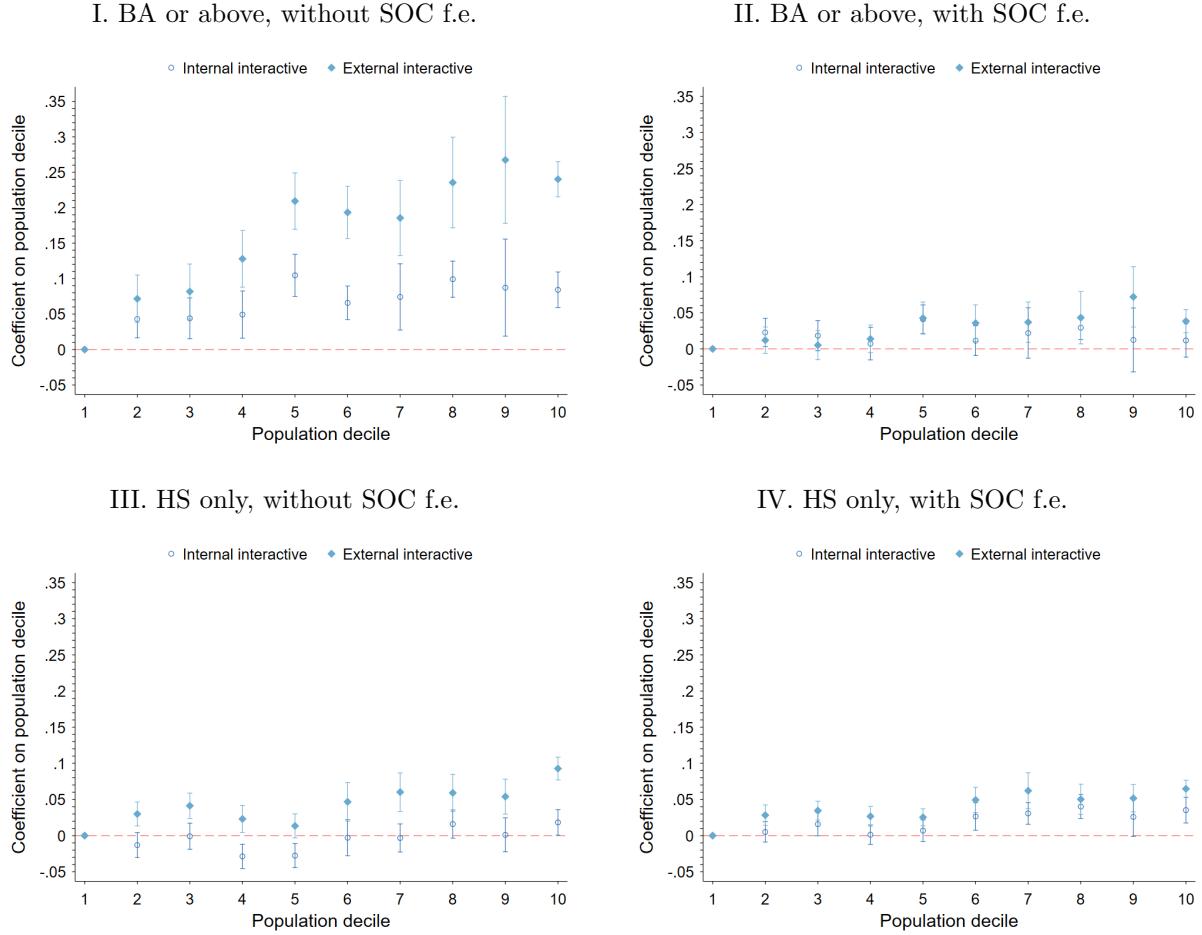

This table checks the sensitivity of Table C.1 to measurement error. To do so, we randomize job ads to population quartiles, based on the actual distribution of six-digit SOCs across quartiles. We then reproduce the decomposition of Table C.1. Since ads are randomized to quartiles, the within shares should be approximately zero.

Figure C.1: Interactive and Analytic Tasks and Market Size

The panels above depict the distribution of jobs across space. To construct the left panel, we first place job ads into one of four mutually exclusive groups, based on whether they are above or below the median non-routine interactive task content and non-routine analytic task content. We then plot the difference between the proportion of jobs in each of the four categories (high or low, analytic or interactive) relative to the proportion of jobs in the same category in the first CZ decile. The right panel is constructed in the same way, except we first subtract the SOC mean task content from each job before placing jobs into groups, and hence the right panel reflects within-occupation changes in task content across space.

Figure C.2: O\*NET Interactive Tasks Gradient

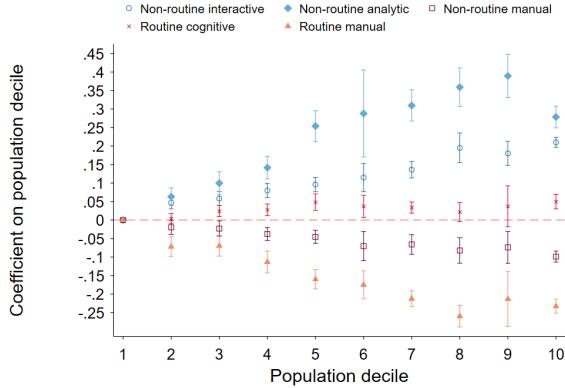

This figure reproduces Figure 2 separately by the educational requirement of the job. Panels I and II restrict the sample to ads requiring a BA or above, while panels III and IV restrict the sample to ads requiring high school only.

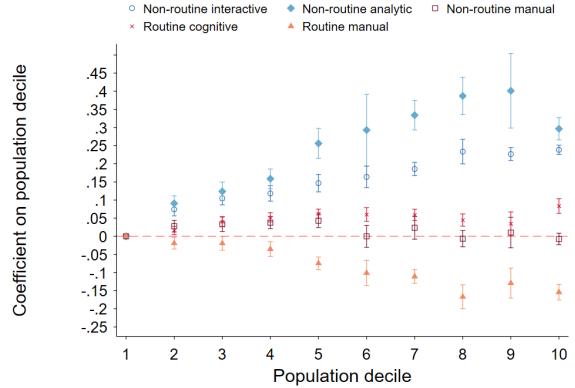

Figure C.3: Tasks and Technologies Gradient by Sample Period

### A. Tasks

I. 2012-2014

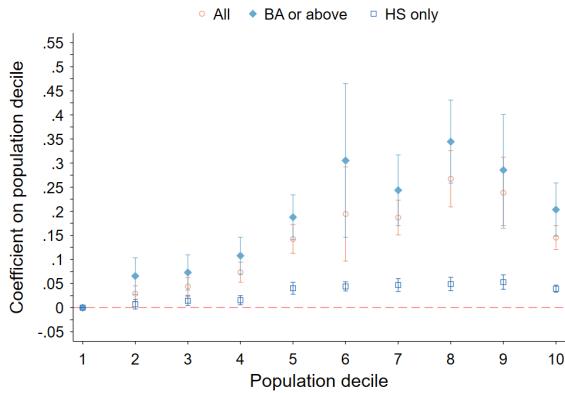

II. 2015-2017

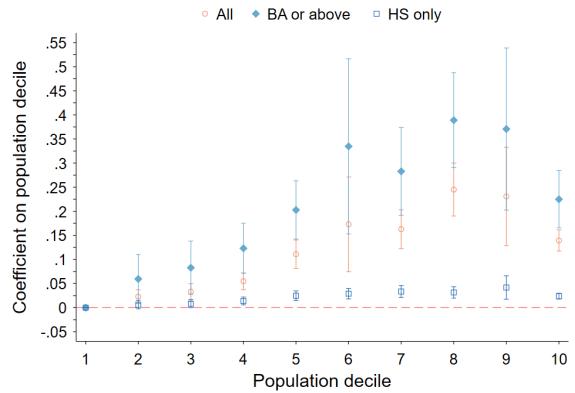

### B. Technologies

III. 2012-2014

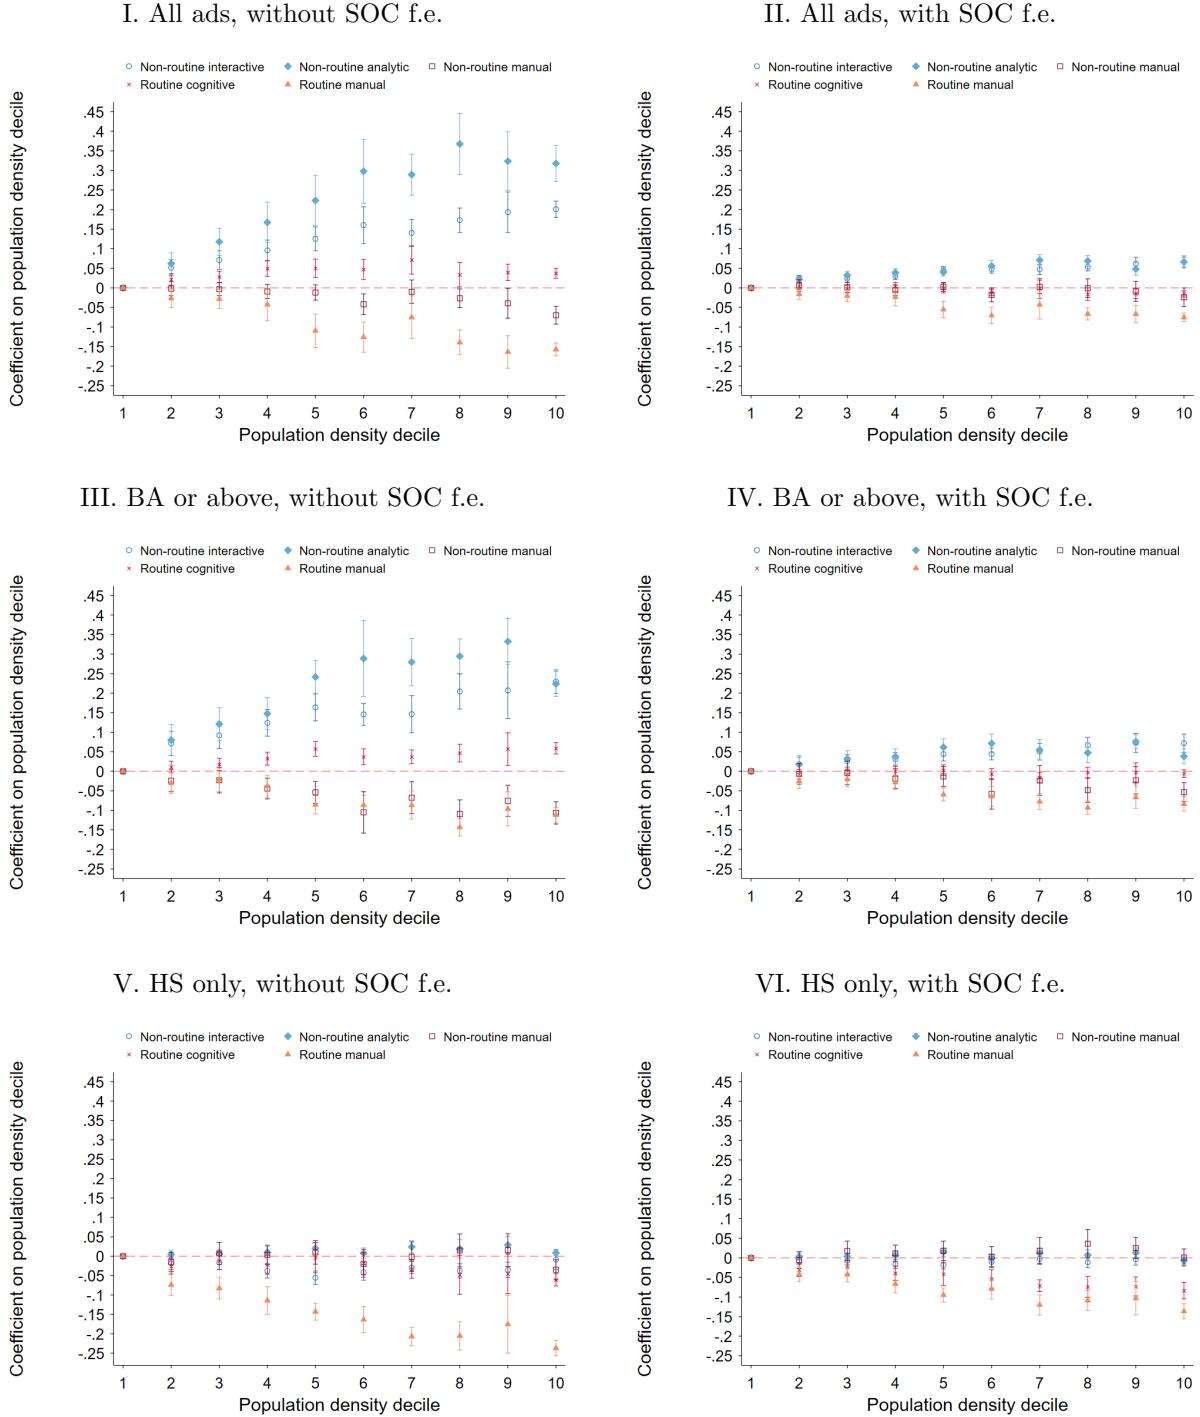

IV. 2015-2017

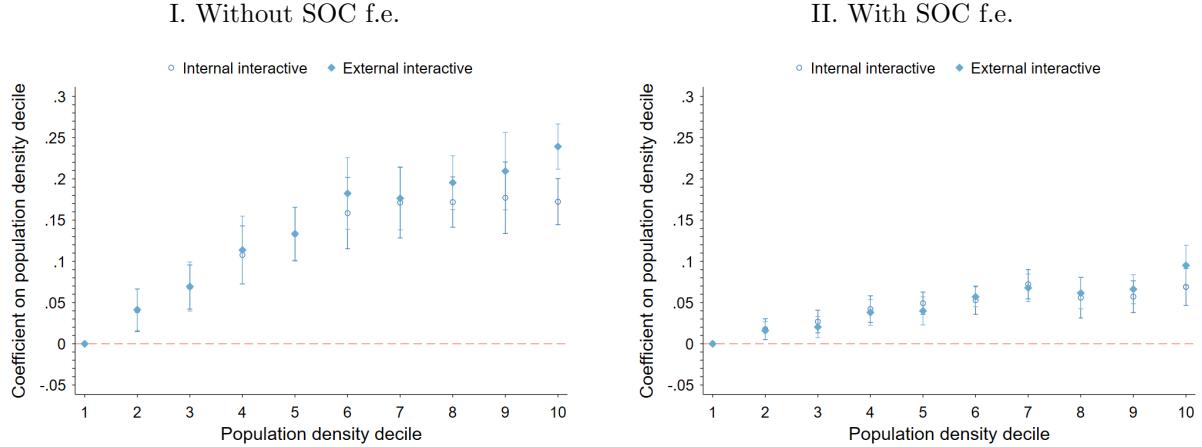

This figure presents estimates of Figure 1, panel I, and Figure 3, panel I, separately by time period. We divide the sample period into 2012-2014 and 2015-2017.

## C.2 Specialization and Market Size

This section provides supplemental evidence on the relationship between specialization within and between firms and market size.

### Robustness to the Number of Tasks

Our measurement approach requires setting a threshold for the number of tasks (verb-noun pairs) we use to study specialization. In the paper, we use a task list of 500 verb-noun pairs, which we winnow to 399 by excluding those that, according to our judgment, do not reflect job tasks.

In this section, we increase the number of tasks to 2,000—a higher resolution—and reproduce Figure 4, the main figure using these granular task measures to study the relationship between specialization and market size. Figure C.8 shows that the results are not sensitive to increasing the number of tasks to 2,000. Figure C.9 reproduces Figure 4 where the specialization measures are based on a task vector of 300—i.e., keeping the most common 300 of our main specification’s 399 tasks. Figure C.9 shows that the results are not sensitive to reducing the number of tasks to 300.

We lastly check the sensitivity of our specialization results to aggregating granular tasks that have similar meanings. The task extraction algorithm produces some distinct tasks that are similar, such as “provide feedback” and “provide recommendations.” Rather than rely on our judgment to determine the similarity of different tasks, we use a natural language processing approach that uses word contexts (from a separate corpus) to aggregate similar tasks. To group our verb-noun tasks into a smaller number of clusters, we follow two steps. In the first step, we convert our list of tasks into a vector representation, using the Word2Vec implementation in the Gensim library for Python. Specifically, we use one of Gensim’s pre-trained models, which was trained on the Google News data set. Using this model, we recover each task’s underlying representation as a 100-element vector.<sup>42</sup> We next add the vector representation of the verb to that of the noun, so as to obtain a single vector for each task. In the second step, we cluster tasks in this vector space, using Stata’s implementation of k-means clustering. The algorithm requires specifying the number of clusters ex-ante, and we experiment with 50, 75, and 100, all of which entail a substantial dimensionality reduction relative to our original list of tasks. We choose 75 task clusters for the exercise presented here, but we note that we examined the sensitivity to this choice to using 50 or 100 task clusters and it has little effect on the results.

Tables C.3-C.4 illustrate how the aggregation works. The tables show the original list of 399 tasks and the corresponding 75 task clusters. The first task cluster the algorithm creates is “identifies problems,” “resolve issue,” and “resolve problems.” The second task cluster includes intuitively similar tasks such as “provide feedback,” “provide recommendations,” “provide guidance,” and “provides leadership,” but also includes tasks we may not a priori view as similar, such as “offer products” or “make offer.” We believe the clustering method does a reasonably good job of aggregating similar tasks in a way that minimizes bias from excess reliance on researcher discretion. Using the 75 task clusters, we calculate task cluster dissimilarities in firm-market and occupation-market cells and reproduce the key

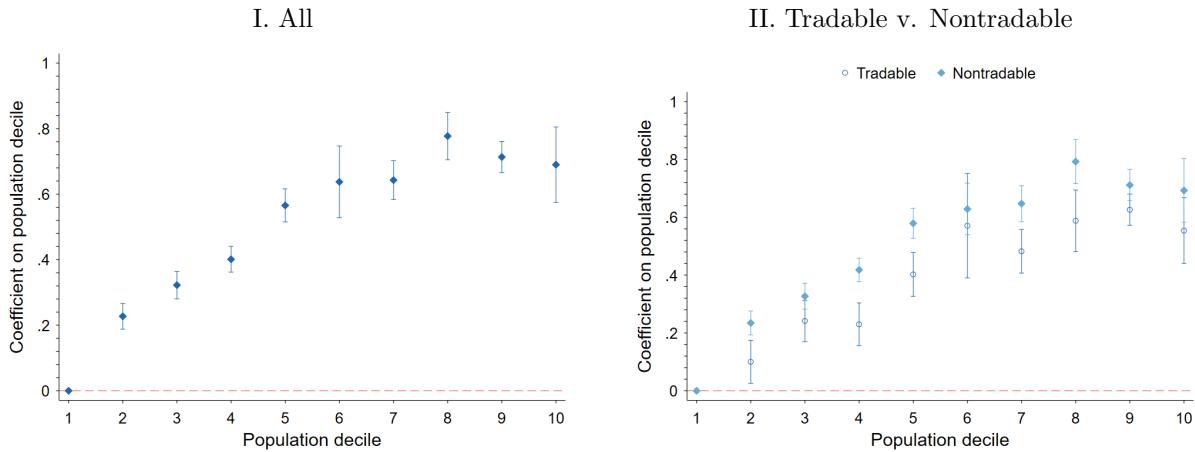

---

<sup>42</sup>This library can be found at <https://radimrehurek.com/gensim/index.html>. The library’s documentation states that the Google News model was trained on “about 3 million words and phrases.” We adopt Gensim’s default for the size of vector representation.

specialization gradients in the paper. Figure C.10 shows the results of this exercise. This figure shows a similar specialization gradient as Figure 4, reinforcing the finding of increased specialization in larger markets.

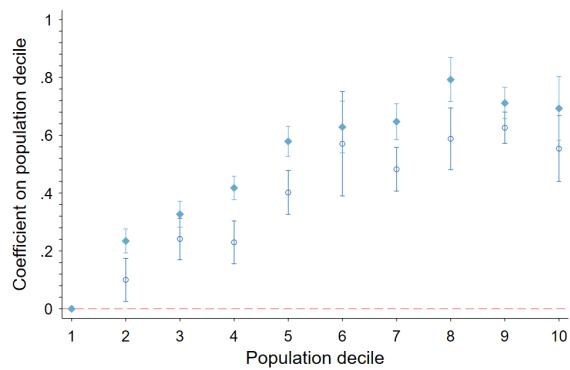

Figure C.8: Specialization Gradient: Task Dissimilarity Within Firms and Occupations (with 2,000 Tasks)

### A. Firms

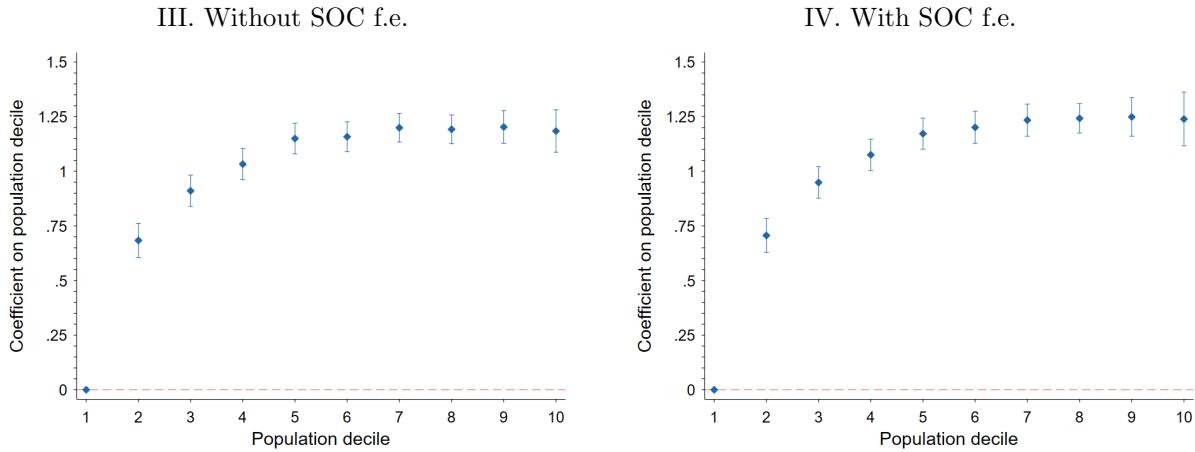

I. All

II. Tradable v. Nontradable

### B. Occupations

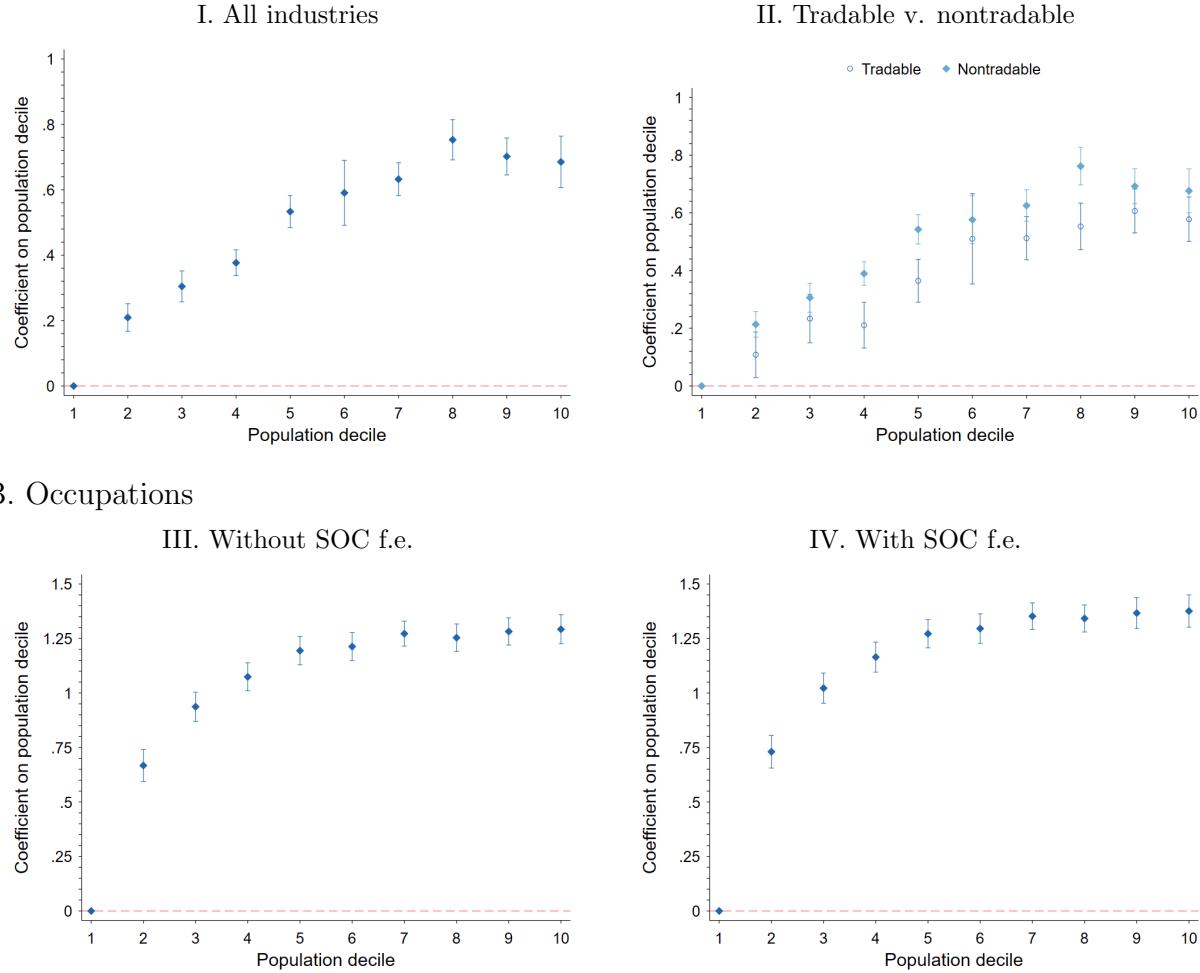

III. Without SOC f.e.

IV. With SOC f.e.

The figure above reproduces Figure 4, except the task dissimilarity measures in the occupation-CZ are constructed based on extracting 2,000 tasks, a higher resolution vector of verb-noun tasks per job ad. For reference, the 1st population decile mean for the top left panel is -0.51, and for the top right panel is -0.54 for the nontradable sample and -0.06 for the tradable sample. The 1st population decile mean for the bottom two panels is -1.00.

Figure C.9: Specialization Gradient: Task Dissimilarity Within Firms and Occupations (300 Tasks)

### A. Firms

This figure reproduces Figure 4 using a task list of 300 verb-noun pairs. For reference, the 1st population decile mean for the top left panel is -0.51, and for the top right panel is -0.53 for the nontradable sample and -0.06 for the tradable sample. The 1st population decile mean for the bottom two panels is -1.06.

Figure C.10: Specialization Gradient: 75 Task Clusters

### A. Firms

I. All

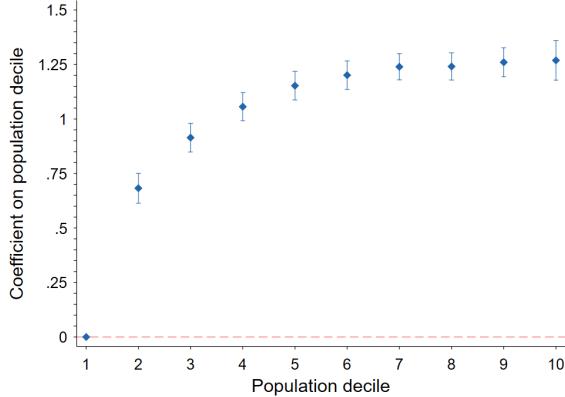

II. Tradable v. Nontradable

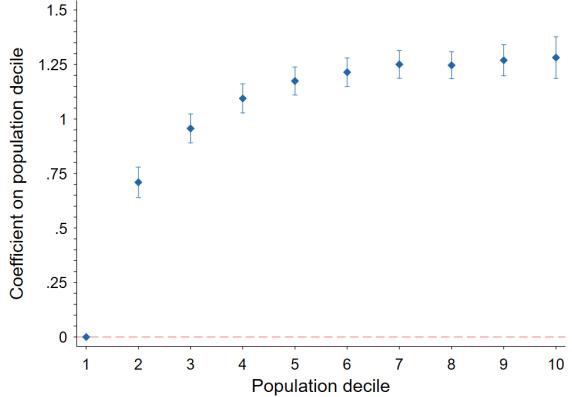

### B. Occupations

III. Without SOC f.e.

IV. With SOC f.e.

The figure above reproduces Figure 4, except the task dissimilarity measures in the firm-market and occupation-market cells are constructed using 75 task clusters. These task groupings are constructed from the original 399 tasks, which are reduced to 75 task clusters using a natural language processing approach described in the text. The 1st population decile mean for the top left panel is -0.50, and for the top right panel is -0.52 for the nontradable sample and -0.04 for the tradable sample. The 1st population decile mean for the bottom two panels is -1.02.

### Measurement Error and Robustness to Controls

Small markets have fewer job ads per occupation-market (or firm-market) cell. Since the resulting within-cell sampling error may systematically vary with market size, one may worry that sampling error may lead us to spuriously conclude that job dissimilarity is increasing in market size. To assess the validity of this concern, we reproduce the key specialization figure in the analysis (Figure 4) with an additional control for the number of ads in the cell. Reas-

suringly, the estimates of this exercise, reported in Figure C.11 below, are virtually identical to Figure 4. We also check the sensitivity of the specialization gradients to measurement error by reproducing panel A of Figure C.12 for firm-market cells with strictly more than the median number of job ads, which is 5, and below or including the median number of job ads.

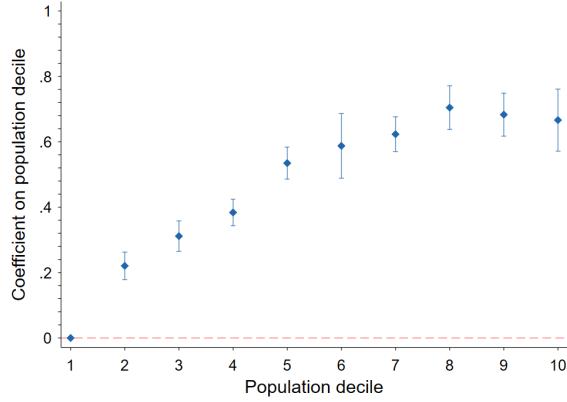

### Placebo-Type Exercise: Analysis of National Chains

We also perform a placebo-type analysis of our specialization gradients for a subset of firms—national chains. To come up with a list of these national chains, we first identify the top 20 company names that have the most job postings. From this list, we identify the chains, which include: Advance Auto Parts, CVS Caremark, Dollar General, Family Dollar, Harbor Freight, Home Depot, Lowes, Macys, McDonalds, Pizza Hut, Sears, Taco Bell, and Wells Fargo. We reproduce panel A of Figure 4 for these retailers (which are all in non-tradable industries) and compare it to all other non-tradable sector firms, which is presented in Figure C.13. The results show a flattened specialization gradient, as we might expect, given the relative homogeneous types of organizational structure of these chains across space. Note that we would not expect the specialization gradient to flatten entirely, since even the workforce of national chains may become more specialized in large markets. Nevertheless, it is reassuring to see a flattened gradient for these national chains.

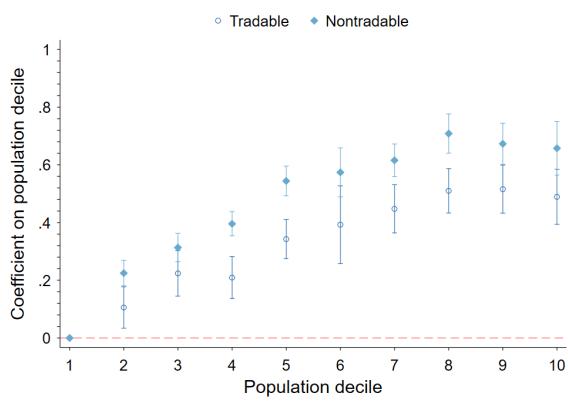

Figure C.11: Specialization Gradient: Task Dissimilarity Within Firms and Occupations

### A. Firms

I. All

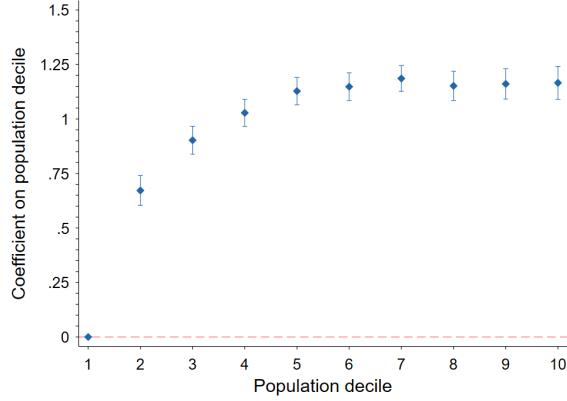

II. Tradable v. Nontradable

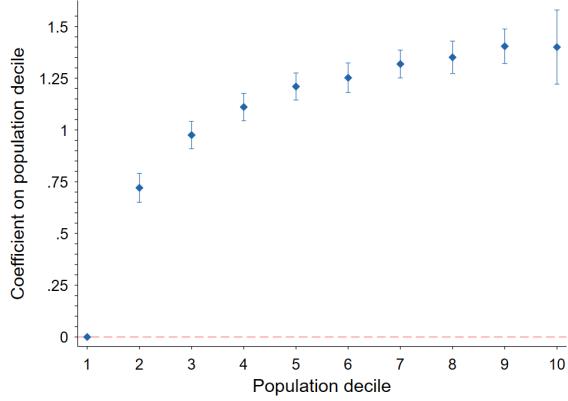

### B. Occupations

III. Without SOC f.e.

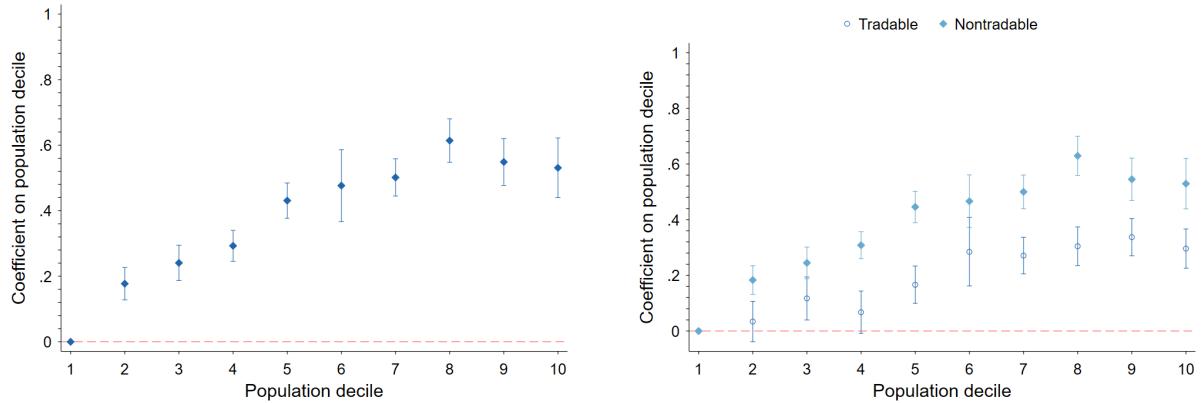

IV. With SOC f.e.

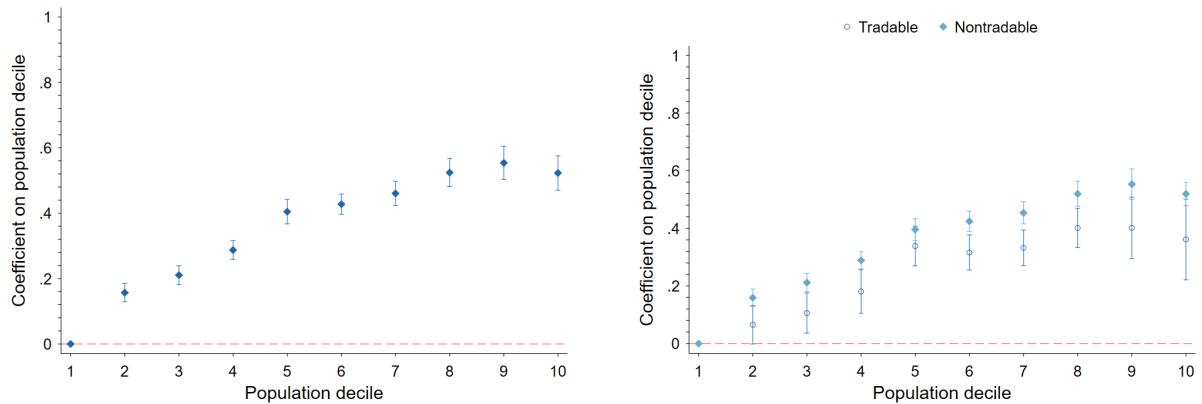

The figures above reproduce Figure 4 with an additional control for the number of ads in the cell.

Figure C.12: Specialization Gradient: Above v. Below Median Firm Size

I. Above Median

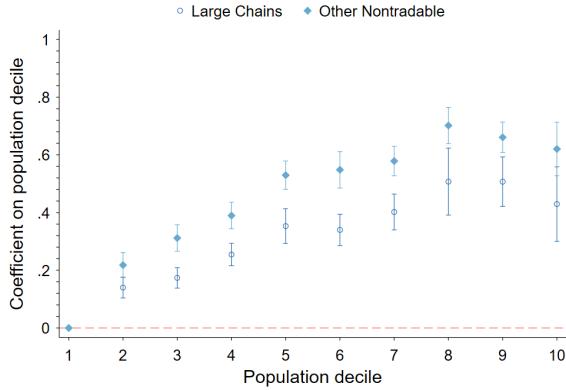

II. Below Median

The figures above reproduce panel A of Figure 4 separately for firm-markets with strictly more than the median number of postings (5) and below or including the median number of postings.

Figure C.13: Specialization Gradient: Large Chains v. Other Non-Tradable

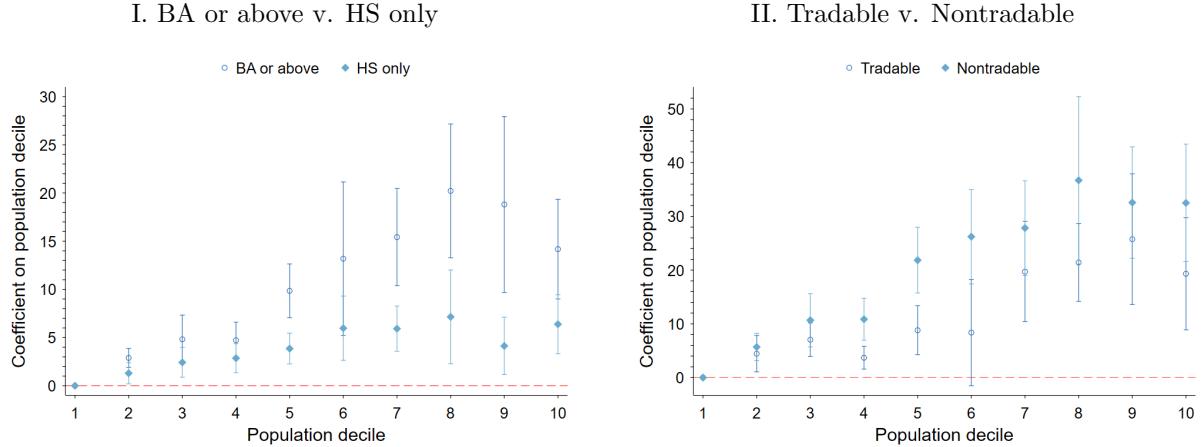

The figures above reproduce panel A.I of Figure 4 separately for large chains (which are all in non-tradable industries) and other non-tradable firms. We control for both log ad words in the cell and two-digit NAICS fixed effects.

### Number of Job Titles

Prior research—notably, [Tian \(2019\)](#)—examines evidence for specialization by counting the number of distinct occupation codes in a firm-market. The idea behind this exercise is that a greater number of distinct occupations implies greater specialization in production. We examine this relationship in Figure C.14, using our job vacancy data to count distinct job titles within a firm name  $\times$  six-digit industry NAICS  $\times$  CZ. We produce these market size gradients separately for high- and low-education-level job titles, and for tradable and nontradable sector firms. The key takeaway is that we do see a positive relationship between market size and the degree of worker specialization, and this relationship is stronger for workers with a BA degree or above and for nontradable sector firms.

Figure C.14: Specialization Gradient: Number of Job Titles

The unit of observation is the firm-market (CZ). We regress the number of distinct job titles on market size deciles, controlling for the total number of ads placed by the firm in the CZ, two-digit NAICS code, and the average log ad length. The left panel depicts two regressions. In the first, the dependent variable is the number of job titles requiring a high school diploma, and in the second, the dependent variable is the number of distinct job titles requiring a college degree. In the right panel, the dependent variable is the number of distinct job titles, and the regression is estimated separately on tradable and nontradable sector firms. All regressions are weighted by the number of ads in the firm-market. Standard errors are robust and clustered at the CZ level. The figure plots the coefficients on the CZ size deciles. For reference, in the left panel, the 1st population decile mean for BA or above is 2.58 and for HS only is 3.11. In the right panel, the 1st population decile mean for tradable is 9.96 and for nontradable is 10.68.

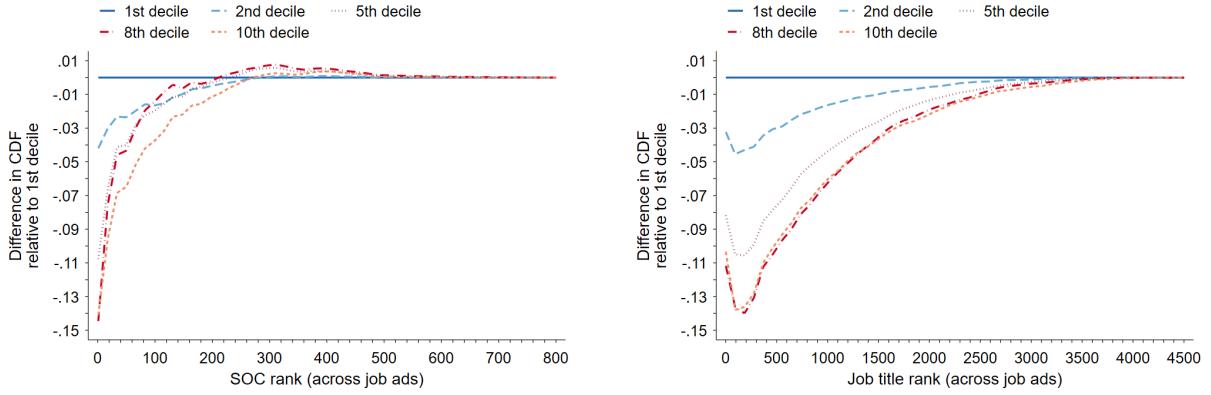

## The Distribution of Common and Rare Occupations

As another robustness exercise, we measure the degree of specialization by examining the distribution of common and rare occupations across space.

We rank six-digit SOCs based on their share of all ads in the full sample. The x-axis presents SOCs in descending order based on their overall rank in the sample. We then compute the share of each SOC in each market size decile and plot the difference relative to the share in the 1st population decile. The left panel of Figure C.15 shows that the most common occupations are overrepresented in small markets, while more rare occupations are overrepresented in large markets. For example, of the 10 most common occupations economy-wide, the 10th decile market has 11-13 percentage points lower share of these occupations compared with the 1st population decile. For the 300-400 most common occupations, the 10th decile market has about a 0.3 percentage point greater share relative to the 1st population decile.

This finding—that rare jobs represent a larger share of total jobs in larger markets—is even more pronounced when we perform the analysis at the job title level. Note that the job title is not observed in standard datasets such as the ACS or the CPS , and hence represents an additional virtue of the job ads data used here. The right panel presents the analysis at the job title level, showing even more dramatically that common jobs are overrepresented in smaller markets (as a share of total jobs).

Figure C.15: Common and Rare Occupations and Job Titles

The left panel is constructed as follows. We first generate the empirical cdf of occupational shares for each CZ decile. On the x-axis, the six-digit SOCs are ranked in order of their shares of all job ads in the sample, from highest to lowest. The left panel presents the difference between each CZ decile cdf and the 1st decile CZ's cdf. The right panel is constructed analogously, except the unit of analysis is the job title rather than the six-digit SOC. A local polynomial smoother is applied to both panels.

### C.3 Robustness of Wage Regressions

This section evaluates the sensitivity of the wage regressions presented in Table 5. We then examine the sensitivity of the wage regression table to two-way clustering of the standard errors, by CZ and four-digit SOC. We then examine the sensitivity of Table 5 to using an alternative task dissimilarity measure—one in which dissimilarity is based on a task vector with 2,000 tasks, a higher resolution of tasks per job ad. Lastly, we examine the sensitivity to including CZ fixed effects.

Table C.5 reproduces Table 5, the main wage regression table, except uses two-way clustering of the standard errors, by CZ and four-digit SOC. The estimated coefficient on task dissimilarity in column 1—the full sample excluding SOC fixed effects—and columns 6 and 7—the sample of blue-collar occupations—lose statistical significance but the overall takeaways of Table 5 are unchanged.

Table C.6 reproduces Table 5 except the task dissimilarity measures in the occupation-CZ are constructed based on a task vector with 2,000 tasks, a higher resolution of tasks per job ad. The results are nearly identical to those in Table 5. Note that the number of observations is slightly higher compared to Table 5. One difference, since longer task vectors are more likely to have a non-zero element, is that there are slightly more occupation-CZ cells with more than 2 job ads that have non-zero task vectors, which is required for the task dissimilarity to be defined and for the occupation-CZ cell to enter the regression. Table C.7 reproduces Table 5 with task dissimilarity measures in the occupation-CZ based on 300 tasks, a lower resolution, and shows similar results.

Table C.8 reproduces Table 5 with CZ fixed effects. The goal is to understand whether specialization and technologies have an effect on wages after controlling for CZ size and other unobserved features of the labor market. Table C.8 shows that with CZ f.e., the coefficient on specialization diminishes. This result is precisely what Smith's theory would predict: It is *through* market size that specialization affects productivity; after controlling for CZ size, the link between specialization and productivity is muted. Nevertheless, the specialization coefficient remains significant with CZ and SOC fixed effects for white-collar occupations in column 5. The interactive tasks coefficient is also diminished once we control for CZ f.e., which is consistent with market size enhancing the relationship between worker interactions and productivity. The technologies coefficient remains statistically significant even with CZ f.e., for the full sample and for white collar occupations.

Table C.5: Task Dissimilarity, Technologies, Interactive Tasks, and Wages (with Two-Way Clustering)

	All			White-collar		Blue-collar

This table reproduces Table 5 with CZ fixed effects.

## C.4 Robustness to Data Source

In this appendix, we reproduce some of our main empirical exercises using a sample of ads from Burning Glass. The EMSI dataset has its own advantages for our purpose. In particular, it contains the ads' raw text, allowing us to isolate the tasks that employers list. In contrast, Burning Glass commingles jobs' skills, technologies, and tasks. Nevertheless, since Burning Glass has been so commonly used in recent analyses of the labor market, we check the robustness of our results to this alternate data source.

We draw a random sample of 1.2 million ads from January 2012 to December 2017. For this sample, so that we can replicate Figure 2, we compute measures of internal-to-the-firm interactive tasks<sup>43</sup> and external-to-the-firm interactive tasks.<sup>44</sup> As in Section 3.1,

<sup>43</sup>We map the following Burning Glass elements to internal interactive tasks: “Agile coaching,” “Communication Skills,” “Employee Coaching,” “Executive Coaching,” “Leadership,” “Leadership Development,” “Leadership Training,” “Mentoring,” “Oral Communication,” “Peer Review,” “Personal Coaching,” “Supervisory Skills,” “Team Building,” “Verbal / Oral Communication,” and “Written Communication.”

<sup>44</sup>We map the following Burning Glass elements to external interactive tasks: “Advertising,” “Client Base Retention,” “Client Care,” “Client Needs Assessment,” “Client Relationship Building and Management,”

we compute the number of task mentions per 1000 ad words. Second, as in Section 3.2, for each ad we compute whether the ad mentions individual O\*NET Hot Technologies. So that we can compute specialization, as in Section 3.3, for each job ad  $j$  we define a 400-dimensional vector,  $T_j$ , with each element characterizing whether ad  $j$  mentions the individual Burning Glass element. As in Section 3.3, we define the normalized task vectors  $V_j = \frac{T_j}{\sqrt{T_j \cdot T_j}}$ , and the distance between job  $j$  and other jobs in the occupation- (or firm-) market as  $d_{jcm} = 1 - V_{jcm} \cdot \bar{V}_{(-j)cm}$ .

First, Figure C.16 replicates Figure 2. As in Section 3.1, external tasks increase in CZ size, both within and between six-digit SOCs. However, potentially due to the smaller sample size, the relationship between CZ size and internal tasks is no longer statistically significant.

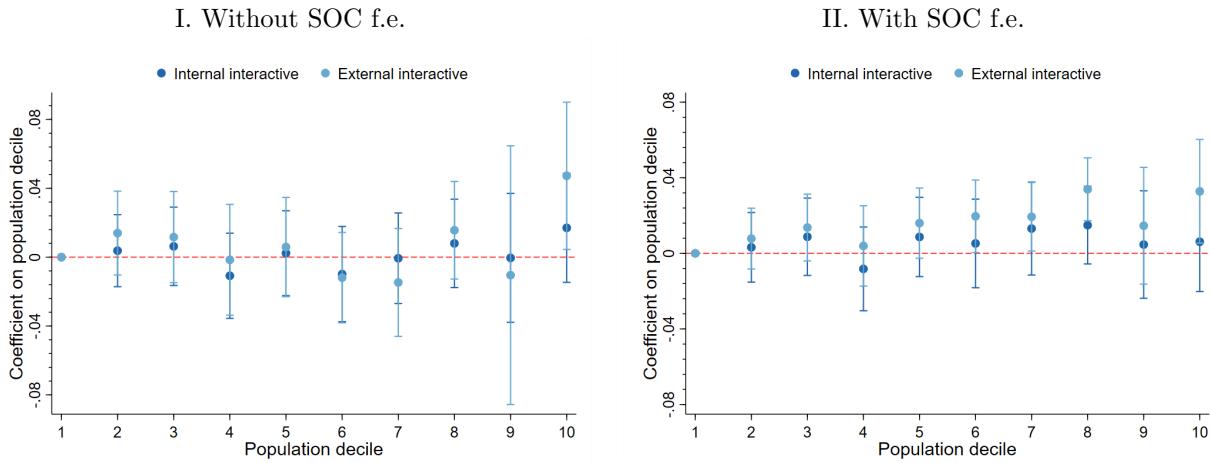

Second, we reproduce Figure 4. As in Figure 4, Figure C.17 indicates that within-occupation and within-firm specialization is greater in more populous commuting zones, with a steeper gradient for firms in nontradable industries than for firms in tradable industries (panel II).

Finally, we reproduce Table 5. As in Table 5, Table C.9 indicates that wages are higher in markets with greater specialization, with greater technology usage, with greater interactive task intensity, and with a greater share of workers with a college degree. Furthermore, also as in Table 5, the relationships between wages and within-occupation  $\times$  market specialization, technology intensity, and interactive task intensity are each stronger in white-collar than in blue-collar occupations.

---

“Communication Skills,” “Digital Marketing,” “Market Planning,” “Marketing,” “Marketing Communications,” “Marketing Programs,” “Marketing Sales,” “Marketing Strategy Development,” “Merchandising,” “Oral Communication,” “Print Advertising,” “Product Marketing,” “Professional Services Marketing,” “Prospective Clients,” “Public Relations,” “Public Relations Campaigns,” “Public Relations Industry Knowledge,” “Public Relations Strategy,” “Sales,” “Telemarketing,” “Vendor Interaction,” “Vendor Performance Monitoring,” “Vendor Relations,” “Verbal / Oral Communication,” and “Written Communication.”

See the caption for Table 5. In contrast, the task dissimilarity and technology measures here come from Burning Glass data.

## C.5 Robustness to Using Posted Wages

To close, we examine the sensitivity of our results to the use of wage data from the American Community Survey. Unfortunately, we are unable to extract information on ads' wages from our EMSI job ad data. Given this, we rely on data from Burning Glass for this sensitivity analysis.

To begin, Tables C.10 and C.11 summarize the share of Burning Glass ads with a posted salary as well as the average (annual) posted salary in the American Community Survey. We find that the share of ads with a posted salary varies systematically by occupation — with 45 percent of Farming, Fishing, and Forestry jobs with a posted salary, compared to 8 percent in Food Preparation and Service — and by CZ population decile — with a larger share of ads with a posted salary in lower population CZs. Second, average wages in the two datasets are highly correlated with one another: Across the 23 two-digit SOCs presented in Table C.10, the raw (unweighted) correlation between log wages in the ACS and in Burning Glass equals 0.95. Across the 10 CZ population deciles, the analogous correlation equals

0.97.

Table C.10: Posted Wages by Occupation

Occupation	Share with Posted Salary	Log Salary	
		ACS	Burning Glass
Management (11)	0.13	11.29	11.14
Business and Financial Operations (13)	0.16	11.18	10.92
Computer and Mathematical (15)	0.12	11.29	11.22
Architecture and Engineering (17)	0.14	11.28	11.10
Life, Physical, and Social Science (19)	0.19	11.14	10.92
Community and Social Science (21)	0.20	10.71	10.71
Legal (23)	0.12	11.49	11.13
Educational Instruction and Library (25)	0.18	10.80	10.65
Arts, Design, and Entertainment (27)	0.13	10.87	10.72
Healthcare Practitioners and Technical (29)	0.10	11.16	11.01
Healthcare Support (31)	0.09	10.27	10.32
Protective Service (33)	0.35	10.85	10.58
Food Preparation and Serving (35)	0.08	10.07	10.24
Building, Grounds Cleaning and Maintenance (37)	0.17	10.15	10.26
Personal Care and Service (39)	0.17	9.96	10.34
Sales and Related (41)	0.07	10.84	10.70
Office and Administrative Support (43)	0.19	10.55	10.44
Farming, Fishing, and Forestry (45)	0.45	10.07	10.28
Construction and Extraction (47)	0.22	10.55	10.65
Installation, Maintenance, and Repair (49)	0.15	10.70	10.58
Production (51)	0.24	10.56	10.42
Transportation and Material Moving (53)	0.19	10.51	10.41
Military (55)	0.39	10.80	10.86

For each two-digit occupation, this table lists the share of Burning Glass ads with a posted salary, average annual (log) wages in the American Community Survey, and (for the subset of ads with a posted salary) average annual wages in the Burning Glass data.

Table C.11: Posted Wages by CZ Population Decile

CZ Population Decile	Share with Posted Salary	Log Salary	
		ACS	Burning Glass
1	0.18	10.55	10.49
2	0.18	10.62	10.53
3	0.17	10.65	10.56
4	0.18	10.69	10.61
5	0.16	10.77	10.64
6	0.16	10.79	10.70
7	0.15	10.85	10.72
8	0.14	10.95	10.81
9	0.12	10.95	10.83
10	0.15	10.86	10.83

For each CZ population decile, this table lists the share of Burning Glass ads with a posted salary, average annual (log) wages in the American Community Survey, and (for the subset of ads with a posted salary) average annual wages in the Burning Glass data.

Finally, Table C.12 reproduces Table 5, replacing ACS with Burning Glass as the source of (log) wages by occupation and commuting zone. (Since only a fraction—less than one-fifth—of ads have a posted wage, both the number of observations and the number of underlying ads represented in this regression table are smaller than in Table 5.) As in Table 5, we find that wages are increasing in task dissimilarity and technology usage, with greater slopes in white-collar occupations. Also as in Table 5, wages are higher in occupation-CZ cells with greater mentions of interactive tasks, though now the coefficients are no longer statistically significant in specifications with occupation fixed effects.

Table C.12: Task Dissimilarity, Technologies, Interactive Tasks, and Wages

	All			White collar		Blue collar	
	(1)	(2)	(3)	(4)	(5)	(6)	(7)
